I would like to dedicate this work to my family for their loving support throughout my life, my son Sean Araz Luca, my wife Jiajun, and my entire research team who have helped me with my discoveries in the fascinating world of color science and technology.

Preface

It is with great pleasure that I present to you the second edition of the *Encyclopedia of Color Science and Technology*, a comprehensive and groundbreaking resource that delves into the intricate world of color. This project brings together the collective wisdom of experts in the fields of color science, technology, physiology, and psychology, providing a valuable reference for researchers, practitioners, and enthusiasts.

Color, as a phenomenon, has captivated our imaginations since time immemorial. Its influence spans a myriad of disciplines, from art and design to physics, biology, and beyond. This new edition of the encyclopedia continues to explore the multifaceted nature of color, examining its scientific underpinnings, technological applications, physiological mechanisms, and psychological implications. Our contributors provide detailed explanations and insights into the principles and techniques that underpin color science. Moreover, the encyclopedia explores the practical applications of color, such as color in imaging, displays, printing, and various industries, demonstrating the profound impact that color technology has on our daily lives.

Understanding color goes beyond its physical and technological aspects. The physiology of color perception and the intricate workings of the human visual system play a fundamental role in how we experience and interpret color. The fascinating realms of color vision, and the neural processes that enable us to perceive the rich tapestry of colors that surround us are among topics examined. Additionally, the psychology of color including the emotional, cognitive, and cultural dimensions of color, as well as its effects on human behavior, perception, and communication are explored. With over 300 new and revised entries, this edition serves as an extension of the authoritative compendium of knowledge in the ever-evolving realm of color science and technology.

I would like to express my heartfelt gratitude to the esteemed section editors who have worked tirelessly to shape this encyclopedia into a definitive resource. Their expertise, dedication, and commitment to excellence have been instrumental in ensuring the accuracy and comprehensiveness of each entry. Their vision and guidance have played a pivotal role in providing entries with unmatched depth and breadth in the domain.

I would especially like to thank Professor Rolf Kuehni for his exceptional leadership as the section editor of two vision science topics. Professor Kuehni's profound knowledge and extensive research in the field of color and his guidance and meticulous attention to detail have been instrumental in ensuring the scientific rigor and accuracy of the entries within this work.

I would also like to extend my heartfelt thanks to Professor Harold S. Freeman, the section editor for materials. Professor Freeman's expertise and profound understanding of colorants and coloration technology have been indispensable in exploring the practical applications and advancements in this arena. His insightful contributions have enriched this encyclopedia, providing invaluable insights into colorants and their various applications.

Furthermore, I would like to express my sincere appreciation to Professor Caivano, the section editor for art and design. Professor Caivano's expertise has greatly enhanced the understanding of how we perceive and experience the artistic aspects of color. Lastly, I would like to extend my deepest gratitude to Professors van Bommel, the section editor for lighting; Professor MacDonald, the section editor for language and categorization; and Dr. Reinhard, the section editor for computer graphics. Their expertise and guidance have helped shape this encyclopedia. Their commitment to excellence and their unwavering dedication to their respective sections have left an indelible mark on this project.

I express my deepest appreciation to all other section editors for their valuable time and effort, contributors, and the entire editorial and production teams who have played a vital role in bringing the *Encyclopedia of Color Science and Technology* to fruition. Their meticulous attention to detail and unwavering commitment to quality have been invaluable in creating a volume that is not only informative but also aesthetically pleasing.

Before concluding, I would like to take a moment to express a personal note. The COVID-19 pandemic has had a profound impact on the world, disrupting various aspects of our lives, including academic and publishing endeavors. The challenges posed by the pandemic, such as restrictions on travel, limited access to research facilities, and remote working arrangements, have unavoidably affected the timeline of this project. Additionally, as the Editor-in-Chief, I faced unexpected health challenges that slowed down the finalization of this volume. I am immensely grateful for the support and understanding extended to me during this time, both from the editorial team and the contributors. Their unwavering dedication and assistance have been invaluable in navigating these unforeseen circumstances.

It is my hope that the *Encyclopedia of Color Science and Technology* will serve as a cornerstone for researchers, educators, and practitioners, inspiring further exploration and innovation in the captivating realm of color. May it illuminate your path and deepen your understanding of the vibrant world of color.

List of Topics

Art and Design

Section Editor: *Prof. José Luis Caivano*

Appearance
Art and Fashion Color Design
Chevreul, Michel-Eugène
Color Circle
Color Combination
Color Contrast
Color Field Painting
Color Harmony
Color in Hospitals
Color in Schools and Offices
Color in Transport
Color Order Systems
Color Pollution
Color Psychology
Color Scheme
Color Trends
Complementary Colors
Environmental Color Design
Functionality of Color
Impressionism
Interactions of Color and Light
Mosaics
Neo-impressionism
Optical Art
Palette
Pastel Colors
Philosophy of Color
Polychromy
Primary Colors
Psychological Color Effects
RYB Color

Tincture
Traditional Color Theory

Color Engineering: Computations

Section Editor: *Gaurav Sharma*

Chromatic Contrast Sensitivity
Clapper-Yule Model
Demichel Equations
Gamut Volume
Vora Value

Color Science: Computations

Section Editor: *Prof. Stephen Westland*

Interpolation of Spectral Data
Transformation of Color Matching Functions

Computer Graphics

Section Editor: *Dr. Erik Reinhard*

Color Transfer
Compositing and Chroma Keying
Global Illumination
High Dynamic Range Imaging
Image Quality
Intrinsic Imaging
Light Stage
Non-photorealistic Rendering
Rendering Natural Phenomena
Sampling Problems in Computer Graphics

Sampling, Reconstruction, Aliasing, and
Anti-aliasing
Stereo and Anaglyph Images
Texture Measurement, Modeling, and Computer
Graphics
Transient Imaging

Language and Categorisation

Section Editor: *Dr. Lindsay MacDonald*

Ancient Color Terminology
Bayesian Approaches to Color Category
Learning
Berlin and Kay Theory
Bilingual Color Naming/Categories
Chinese Color Language
Color Categorical Perception
Color Categories and Vagueness
Color Categorization and Naming in Inherited
Color Vision Deficiencies
Color Categorization: Patterns and Mechanisms
of Evolution
Color Category Learning in Naming-Game
Simulations
Color Constancy and Categories
Color Dictionaries and Corpora
Color Name Applications in Computer Vision
Color Preference
Cross-cultural Communication
Crowdsourcing of Multilingual Color Names
Dynamics of Color Category Formation and
Boundaries
Effects of Color Terms on Color Perception and
Cognition
Evolution of Color Expression
Infant Color Categories
Materials and the Origins of Abstract Color
Naming
Mechanisms of Color Categorization
Memory Color
Mesoamerican Color Survey Digital Archive
Psychological Color Space and Color Terms
Psychologically Pure Colors
Stroop Effect
Translation of Color Language
Vantage Theory of Color
World Color Survey

Lighting

Section Editor: *Prof. Wout van Bommel*

Architectural Lighting
Automotive Front Lighting System (Status 2020)
Autonomous Vehicle (AV) Lighting Systems
Blacklight Lamp
Carbon Arc Lamp
Coefficient of Utilization, Lumen Method
Combustion Lamp
Daylight Factor
Daylighting
Diffuse Lighting
Electrical Control Gear for Lamps
Emergency Lighting
Halogen Lamp
High Pressure Mercury Lamp
High- and Low-Pressure Sodium Lamp
Human-Centric Lighting
Incandescence
Incandescent Lamp
Induction Lamp

About the Editor

Renzo Shamey has been actively involved in the field of color science and technology since the early 1990s. His significant contributions in this domain encompass the development of datasets for color difference modeling, exploration of unique hues, blackness, whiteness, and investigation of sources of variability in perceptual assessments of color and color differences. Additionally, his research has focused on the automation of the coloration process and the implementation of artificial intelligence for diagnosing faults. He has also created undergraduate and graduate courses in color science and coloration, delivering lectures at prestigious universities in the United States, Europe, and Asia.

Professor Shamey has authored or co-authored over 250 peer-reviewed manuscripts, book chapters, monographs, and notable books such as *Modelling, Simulation, and Control of the Dyeing Process* (2014) and *Pioneers of Color Science* (2020). Furthermore, he has successfully supervised more than 30 PhD students who have made significant contributions to color science and technology.

Professor Shamey has actively participated in various color organizations including, but not limited to, the Society of Dyers and Colourists (SDC), the Inter-Society Color Council (ISCC), the American Association of Textile Chemists and Colorists (AATCC), and the International Commission on Illumination (CIE). Notably, he served as the president-elect, president, and past president of the ISCC from 2018 to 2022. He has also held positions such as the Chair of the Color Measurement Test Methods Committee (RA36)

at AATCC from 2011 to 2014 and has been a member of several technical committees.

In 2014, Dr. Shamey was selected as a North Carolina State University Faculty Scholar. His contributions have been acknowledged through several awards, including the Gold Medal from the Worshipful Company of Dyers for a research paper he co-authored (2009), the AATCC JW Weaver Award for the Best Paper of the Year (2012), and the Fellowship of the Society of Dyers and Colourists (2000). Currently, he is the CIBA distinguished Professor of Color Science and Technology at North Carolina State University in the United States and is also an Honorary Professor at Tiangong University in China.

Adaptation

Susan P. Farnand

Program of Color Science, Rochester Institute of Technology, Rochester, NY, USA

Definition

The human visual system receives and interprets an enormous volume of information regarding the environment in which the individual is immersed. Indeed, there is more information available than can be processed. This includes information on whether it is day or night, sunny or cloudy, how fast objects around us are moving and whether an approaching person is happy or angry. A degree of normalization of human vision is of critical importance in establishing in the brain and mind a tool for recognizing objects or people despite the extensive variations in physical stimuli that the visual system encounters. The term used to identify this tool and its many aspects is “adaptation.” Adaptation processes occur throughout the visual system, from the pupil to the brain, with the results accessible to the conscious mind. Webster cites the key functions of adaptation as efficient coding of the incoming visual information, including enhancement of novel stimuli, and appearance needed for

recognition [1]. The general subject of adaptation also applies to sensory systems other than vision.

Adaptation

Visual adaptation processes have developed over many millions of years by evolutionary processes, with the details varying between different advanced species of creatures, depending on their visual systems and the world they inhabit. The human adaptation system is known to be complex in detail with many aspects not yet fully understood. One of its purposes is to adapt incoming stimuli representing known objects in a way that the perceptual appearance of these remains very similar for most natural conditions in which they are viewed. Adaptation is understood as an efficient way to code physical information entering the visual system through the eyes in a manner that results in a reasonably constant perceived appearance of known people and objects while retaining enough information to preserve the context in which we find them.

Adaptation processes are applied by the visual system at different stages of the viewing process, thereby having potential impact on all perceptual aspects, from the retina in the eyes to the mind via various levels of activity in the brain, influencing the final perceptions in the mind. Important functions of adaptation at earlier stages are enhancing discrimination, highlighting visual novelties, maintaining perceptual constancy, producing efficient vision coding, getting extensive information from neurons with very limited dynamic ranges, and ensuring that neurons at lower levels in the system are not under- or overexposed [2]. Fairchild [3] lists a number of mechanisms from the eye to the mind that are thought to be involved in the adaptation process including pupil diameter, depletion and regeneration of photopigments, transition from cones to rods, pooling of photoreceptor input, opponency effects, gain control in receptors and higher-order mechanisms, and cognitive effects.

In the International Lighting Vocabulary of the *Commission Internationale de l'Eclairage* (CIE), the term adaptation is defined as "Process by which the state of the visual system is modified

by previous and present exposure to stimuli that may have various luminance values, spectral distributions, and angular subtenses" [4]. This definition suggests that modifications to the visual system can occur due to shifts in luminance (dark and light adaptation) and spectral distribution (chromatic adaptation). These visual adaptation processes are significant for human color perception and are briefly discussed below.

A thorough, recent review by Webster of the present knowledge about visual adaptation, as well as key current questions pertaining to it, is found in Ref. [1].

Dark and Light Adaptation

Both concepts deal with the fact that natural light levels on the earth can vary more than a million-fold in intensity during a 24-h day cycle (from a dark night to a bright, sunny day). Our visual system can compensate for small changes in light level very quickly so that we are not aware of them; when the changes are large, such as when moving from a dark, windowless room into bright daylight (or vice versa), the visual system may take up to an hour to completely adjust to the change. The range of response of neurons to light stimuli, for example, in the ganglion cells of the retina, runs from zero to about 200 spikes per second. This is a very small range to account for the required millionfold range in light intensity. Some control systems have developed to overcome this limitation: one is the pupil size in the eyes that can range in diameter from about 2 to 8 mm; it increases the area in which light can enter an eye by a modest factor of about 16. Another supporting system is having two types of sensors in the eye with much different sensitivities to light. These are the rods, active in night vision, and the cones, active in daylight vision. Depending on the light intensity, one or both can operate, both being active in twilight illumination.

Dark adaptation refers to the situation when an observer transitions from exposure to bright light to darkness. If this transition is abrupt, the ability to perceive objects and their differences in color disappears initially and nearly completely. Figure 1 illustrates how the visual sensitivity

Adaptation, Fig. 1 Dark adaptation curves for test stimuli of various wavelengths: RI (680 nm), RII (635 nm), Y (573 nm), G (520 nm), V (485 nm), and W (white light). (Chapanis' data from Bartlett [6])

threshold changes during dark adaptation following a photoreceptor bleaching exposure. The upper part of the curves represents the recovery of the cone receptors, showing a rapid drop in threshold over several minutes before leveling off. After about 10–15 min, depending on the spectral content of the stimulus, the rod photoreceptors recover enough sensitivity (except for the longest wavelength stimulus) such that visual system shifts to rod receptor operation, lower part of the curves. For a white light stimulus, the break point can vary between about 7 and 10 min, depending on the observer [5]. Over 20 min of recovery time are required to obtain optimal visual sensitivity of the rod receptor vision system.

Light adaptation describes the opposing situation where the observer moves from exposure to darkness into brightly lit surroundings with the resulting change in visual sensitivity again measured as it changes over time in the bright surroundings. In these conditions the time for recovery of visual sensitivity is much shorter (6–8 min) than in dark adaptation because the cone sensory system recovers more quickly [7].

There are a number of factors influencing dark and light adaptation with the results, in terms of

visual sensitivity, varying noticeably. These can include environmental factors, such as overall light level and saturation level of the adapting stimuli, and characteristics of the observer, particularly age. Based on the large number of variables that can have an effect on adaptation, some researchers have created “adaptation metamers,” different stimuli that produce the same level of dark or light adaptation, in order to more precisely study the adaptation processes [1].

Given the considerable effect that variation in luminance or lightness has on the appearance of colored lights or objects, mathematical color appearance models often include adjustments to produce appearance predictions comparable to the references stored in the observer’s brain [2].

Chromatic Adaptation

Interaction of light with the sensor photopigments results in their bleaching to a smaller or larger degree, requiring a process of regeneration that takes some time. Humans have three kinds of cones in their visual systems, which allows relative adjustment in color perception in different

Adaptation, Fig. 2 An illustration of spatially localized chromatic adaptation. Stare at the dot between the blue and yellow patches for at least 15 s without moving your eyes. Now look at the white area. What do you see? Adapting to yellow fatigues the photoreceptors relative to their response to yellow, resulting in a bluish appearance. The

environments. Such relative temporary bleaching of the three cone types is also responsible for the dramatic afterimage effects seen when chromatic color samples are fixated for some period of time with the fixation then changing to a well-lit white

opposite occurs for blue. Repeat the process, this time, after adapting to the patches, look at the black dot in the photograph. By adjusting the adaptation time, you should be able to make the two halves of the photograph blend together

paper. Fields perceived originally as having a blue color now appear as having a yellow color and with comparably opponent color pairs in other cases. These afterimages also illustrate that chromatic adaptation is spatially localized on the

retina, sometimes referred to as local adaptation. In normal viewing conditions, the bleaching effects are much smaller, and in color perception these effects are normalized by an adaptation process.

That humans have three kinds of cone photoreceptors makes it possible for them to distinguish between a huge number of varying light compositions arriving at the eyes, and thereby also between objects. This situation requires chromatic adaptation so that the perception of known people and objects is adjusted to be similar to what is stored in the mind/brain and they are not considered new and different objects or people. In addition to relative bleaching of the three cone types, this adaptation can be achieved through relative gain control in the horizontal, bipolar, and ganglion cells in the retina as well as higher-level mechanisms beyond the retina [3].

An example of chromatic adaptation, as described by Fairchild [3], is that a piece of white-appearing paper viewed in average daylight still appears white when viewed in tungsten light, even though the colorimetric definition of the reflected energy absorbed by the eyes has changed considerably, as would also be the case if the paper is viewed in various other illumination colors. These results are based on chromatic adaptation effects automatically active in the normal human brain.

Over more than a century, a number of mathematical models have been developed to predict chromatic adaptation situations on basis of colorimetric data. One of the first and most influential models was introduced by J. von Kries (1902). Since then several new models have been proposed, among them the Land Retinex theory model (1977), the Nayatani model (1981), Guth's model (1985), and Fairchild's model (1990). All of these are based on L, M, S cone response data. Starting in the late 1990s, the CIE began to propose complex color appearance models that include chromatic adaptation, beginning with CIECAM97. An improvement of the latter was issued as CIECAM02 in 2002 [8]. This model is still in use though it has been further optimized. Detailed descriptions of these and additional models are found in Ref. [3].

Spatial Adaptation

In addition to colorimetrically related adaptation, humans adapt to spatial characteristics including motion, blur, optical noise, and facial expression. An example of spatial adaptation is shown in Fig. 3. These have been demonstrated to exist in the human visual system, thereby assuring that related information is adjusted in the brain and mind, such as eliminating unrecognizable information due to motion, to a blurred image, or to general optical noise and, in facial images, assuring that the person involved is recognized correctly. But the neural processes in the human visual system that underlie adaptation are not yet fully identified and understood. This is on the list of future issues Webster includes in his review of visual adaptation [1]. The list also includes questions with regard to the limits of adaptation and an emphasis on evaluating how observers adapt to a more realistic visual world, as opposed to laboratory environments, including more complex visual stimuli. Snow et al. provide a review of research being conducted on visual adaptation with natural stimuli [9]. And McIntosh et al. present research on using convolutional neural networks to model retinal responses to natural scenes [10].

One additional topic of research pertains to the possibility of individual differences in adaptation. With the known differences in color matching functions along with the cognitive effects involved in adaptation, it seems reasonable to expect that individual observers would experience differences in how they adapt to given environments. Indeed, a computational study suggests the possibility for statistically significant differences in the adaptation processes among observers [11]. However, more extensive experimental data on metameric color matching and corresponding colors is needed to evaluate the extent of individual differences in adaptation.

Summary

Adaptation is an essential tool for the efficient and effective processing of the information available to human sensory systems. As Webster summarized the issue, "Adaptation operates throughout

Adaptation, Fig. 3 This figure provides an illustration of spatial adaptation. Direct your gaze to the horizontal black bar between the two sets of vertical bars in (a). Move your eyes back and forth along the bar for about a minute. Now fixate on the dot between the two sets of vertical bars in (b).

What do you see? The bars on the left of (b) should appear to be closer together than those on the right although the two sets of bars are identical. (After Fairchild Chapter 8, Figure 8.5 [3])

most, if not all, levels of sensory coding and thus impacts all aspects of perception. Adaptation probably serves a variety of related functions, ranging from increasing coding efficiency to supporting perceptual constancy and highlighting novel information” [1]. It is evident that more research is required to develop a more complete understanding of its processes (Fig. 2).

Definition

An afterimage is an image that continues to be perceived after the physical stimulus that it originated from disappears from the observer’s visual field. The afterimage can be a result of an exposition to a grayscale pattern, a colored pattern, or even to a motion stimulus. There are different kinds of afterimages, for example, the positive one will be the same with the physical stimulus, while the negative one will result in the opposite in terms of luminance, colors, or direction of the physical stimulus that generates it.

Introduction

In everyday experience it is not so uncommon to experience several types of aftereffects. The observation done by Addams [1] while watching a waterfall near to the Loch Ness in Scotland is probably the most famous description of the motion aftereffect outside a scientific laboratory. The motion aftereffect was already observed by Aristotle and Lucretius in the ancient times, but the description done by Addams remains the most cited example: if an observer watches a fall for about 60 s and, after that, moves the gaze to the woods nearby, everything will seem to move upward. Now it is known that motion aftereffects can be so powerful that they can influence the apparent direction of the illusory motion produced by static patterns, [2] even if generated after only milliseconds of adaptation [3].

Possible Explanations

However, it is not just adaptation to motion that produces aftereffects. Although an afterimage can be easily experienced after looking for a prolonged period of time at a grayscale image, the most popular afterimages are probably experienced after looking at a colored image. Staring at the fixation cross in Fig. 1 for more than 30 s and then moving the gaze to a white surface should produce a color negative afterimage: the disks will appear filled with the complementary colors of the

Afterimage, Fig. 1 In order to experience a color negative afterimage, the reader should stare at the fixation cross shown for no less than 30 s and then move the gaze to a white surface. What should be seen on the blank surface are four circles filled with the opposite colors (the *green* should be now *red*, the *blue* *yellow*, the *yellow* *blue*, and finally the *red* *green*)

original stimulus on the blank surface. The common opinion in the scientific community is that the afterimages result from neural adaptation, but adaptation is present throughout the visual system, which makes the neural substrate of these phenomena not so easy to isolate. For long, it was supposed that the afterimages were caused by fatigued cells in the retina responding to light. Then, if an observer will stare at the red color for enough time, the receptors in the retina responding to red will fatigue and will fire less. In color vision, it is generally believed that colors are represented along orthogonal opponent axes: yellow to blue and red to green. Consequently, when the observer will switch over to a white surface, after that the retinal receptors for red stimuli are adapted, the visual system will interpret that blank surface as filled with the red complementary color: green. This oversimplified explanation where all the color afterimages are explained at the retinal level was successively challenged by several phenomena that required cortical elaboration [4]. In the 1960s it was shown that the rabbit visual cortex presented

neural adaptation after prolonged exposition to a stimulus that was comparable to the duration of the aftereffects recorded during the psychophysical experiments [5]. These results, in agreement with other neuropsychological and psychophysical studies [4], moved the possible main physiological substrate of the afterimage into the primary visual cortex (V1). V1 is also able to explain the interocular transfer of the aftereffect, which is the possibility to adapt an eye and to observe some effects on the non-adapted one.

However, even if low-level cortical processes seem perfectly appropriate to explain the afterimage, the discovery that the top-down processes are able to influence radically both the primary visual cortex and also some subcortical “stations” of the visual system, such as the lateral geniculate nucleus (LGN), together with some new types of aftereffects that show the influence of attention [6, 7], consciousness [8], or an effect that lasts for days, weeks, or even months, seemed to clearly reject an explanation in terms of the short-lived adaptation reported typically in single cells of V1. These effects all suggested that the final percept of the afterimages is probably a complex result of the interaction and the adaptation of several subsystems throughout the visual system from the retina to the high-level cortical areas. Recently it was shown that the color afterimage signals are generated in the retina, but they are modified by cortical processes [9]. In sum the retinal afterimages face a destiny similar to that of all the retinal signals: in humans they are virtually always heavily modulated by the cortex.

An interesting question that can be posed, however, is whether the afterimages have a function or if they are just a side effect incurred as a minor consequence of having evolved such a complex and superb machinery known as the human visual system. The answer, as probably expected, seems to be that the afterimages, and neural adaptation in general, are part of complex neural strategies evolved during thousands of years in order to improve our perception of the world (e.g., [10, 11]).

Breathing Light Illusion

Finally the afterimage (with color or in grayscale, it depends on which version is used) is also at the basis of the family of illusions composed of the breathing light illusion and the dynamic luminance-gradient illusion [12–14]. Approaching these patterns like the one in Fig. 2 by moving one's head toward it makes the spot appear to become larger, more diffuse, and filled with white. On receding from it, the spot's center remains white, but the remainder appears smaller, darker, and sharper. The proposed explanation of the phenomenon is related to the superimposition of the afterimage on the physical stimulus during dynamical viewing [13, 14].

In summary the afterimages are interesting phenomena that help to understand some of our brain mechanisms. They are able to produce striking illusory effects. The underlying mechanisms appear to be relevant in producing a more efficient perception of the world.

Afterimage, Fig. 2 A complex version of the breathing light illusion. Approaching the patterns by moving one's head toward the image makes the spot appear to become larger, more diffuse, and filled with white. On receding from it, the spot's center remains white, but the remainder appears smaller, darker, and sharper. In addition, in this specific pattern, an illusory rotation is perceived together with the typical illusory effect of the breathing light illusion. This illusory rotation is the same as experienced in the Rotating-Tilted-Lines Illusion [15–18]

Age-Related Changes of Human Seeing Abilities

► Vision and Age

Al-Biruni

Eric Kirchner
Kirchner Publications, AJ, Leiden,
The Netherlands

Abu'l-Raihan al-Biruni was a Persian polymath born in 973 AD. His contributions to mathematics, geography, astronomy, and physics are most well known. During his travels in India, he not only taught Greek science, but in exchange he became acquainted with Indian science. This made him a strong promoter of this science in the Islamic world.

At the court of sultan Mas'ud, al-Biruni wrote an important work on minerals and gemstones, called the *Kitab al-jamahir fi ma'rifat al-jawahir* (The book of the multitude of knowledge of precious stones) [1–3]. In this lapidary, al-Biruni gives a detailed description of the colors of many minerals and gemstones. Color is used as a clear way to identify minerals and gemstones. He discusses extensively the slight color differences between minerals originating from different mines or having different degrees of purity, relating them to the effect this may have on their financial value.

The *Kitab al-jamahir* does not contain a separate chapter on color itself or on color ordering. But taken together, the many descriptions of color

variations that appear in this book while discussing different types of minerals and gemstones do form a large body of scientific knowledge on color. Two centuries after al-Biruni, another Persian scientist by the name of al-Tusi would indeed collect many of al-Biruni's findings and formulate an impressive color ordering scheme by combining them with other sources [4].

An example of this part of al-Biruni's scientific legacy is found in his description of different types of rubies. According to al-Biruni, the colors of rubies range from sky blue, via lapis lazuli and indigo-blue, to kohl black. Almost exactly the same color series is found in the grand color scheme of al-Tusi, with only the color turquoise having been added. In a similar way, not only many color words in al-Tusi's grand color scheme already occur in al-Biruni's work, but the latter also provided several partial color orderings.

Another interesting aspect of al-Biruni's description of color is that he is one of the first to verbally describe one of the color dimensions. After having described the color series from sky blue, via lapis lazuli and indigo-blue, to kohl black, al-Biruni characterizes this gradual color change by the word *shab'a* (p. 72 in Ref. [1]) (Vol. 2, p. 42 in Ref. [5]). Originally this word is used for describing the feeling one has after a copious meal, and it is best translated as saturation. In classical Arabic literature and in modern Arabic, the same word became the common word for color saturation (p. 701 in Ref. [6]). Although the color sequence mentioned above shows that the colors in this series do not change only with respect to color saturation in the modern definition of this word, al-Biruni's text is one of the first to relate this term to color [7].

Al-Farisi, Kamal al-Din Hasan ibn Ali ibn Hasan

Eric Kirchner¹ and Seyed Hossein Amirshahi²

¹Kirchner Publications, AJLeiden,
The Netherlands

²AUT Textile Department, Amirkabir University
of Technology, Tehran Polytechnic, Tehran, Iran

At the end of the thirteenth century, Kamal al-Din Hasan ibn Ali ibn Hasan al-Farisi studied at the school of Tabriz (Azerbaijan, Iran). His teacher was the famous astronomer Qutb al-Din al-Shirazi, who in turn was a student of Nasir al-Din al-Tusi.

Al-Farisi felt “perplexity” when he found several inconsistencies and errors in the classical works about optics [1]. His teacher then managed to obtain a manuscript copy of the *Kitab al-Manazir* from Ibn al-Haytham, which was brought in “from a very distant land” (probably Egypt). Al-Farisi was greatly impressed by this work and decided to write a detailed commentary on it. He discussed it in great detail and completed it by adding appendices with other optical writings. Al-Farisi also included corrections to these texts, aptly calling the resulting work *Tanqih al-Manazir* (Revision of the [*Kitab*] *al-Manazir*) [2].

In one of al-Farisi's comments in the *Tanqih*, he described how an object is seen in a certain color under sunlight, but in a different color under moonlight, and yet in another color in the light of fire. From this, al-Farisi concluded that colors are not really present in objects, but depend on

illumination [3]. The role of incident light had therefore been changed from being a mere catalyst for color vision as in the ancient Greek theories to being as prominent as in modern color theory [4].

Together with his teacher Qutb al-Din al-Shirazi, al-Farisi tried to find explanations why the famous experiment of Ptolemy, with a spinning top (or mill stone) having sectors painted in different colors, led to new colors [5].

Regarding the colors of the rainbow, Ibn al-Haytham had supported the Aristotelian idea that these were due to a mixture of light and darkness. Al-Farisi rejected this concept. He argued that if it was true, then the colors of the rainbow would be ordered from bright to dark. Also, the secondary rainbow would then have the same color order. Both are not supported by observation [6].

But al-Farisi would become most famous for his experimental study of the formation of rainbow colors. Inspired by Ibn Sina's work and by Ibn al-Haytham's *Kitab al-Manazir* and the latter's treatise on the burning glass sphere, he filled a glass sphere with water and considered this as a model for a droplet of rain water in the atmosphere. He then studied the resulting reflection and refraction of light in a dark room (see Fig. 1). This led him to the first correct explanation of the colors of the rainbow, which he described in the *Tanqih*. Interestingly in Germany, at approximately the same time also Theodoric of Freiburg, equally inspired by the *Kitab al-Manazir*, carried out the same experiment and formulated the same conclusions.

It was recently discovered that in his *Tanqih*, al-Farisi included the text of al-Tusi on color ordering, in which five paths were proposed to go from white to black [7]. In this way, this text would become available to many later generations. Al-Farisi also sought for an explanation of the different orderings of the colors in the primary and secondary rainbow. His dark room experiments let him conclude that the various colors of the rainbow were produced by a superposition of different images as projected after reflections and refraction in the sphere [8]. Thereby, the colors became a function of the positions and luminous intensities of the composing images [9].

Al-Farisi, Kamal al-Din Hasan ibn Ali ibn Hasan, Fig. 1 Double refraction and single reflection in a raindrop. Simultaneously with Theodoric of Freiberg, al-Farisi was the first to give the correct explanation of the rainbow in his *Tanqih al-Manazir* (©Library of the Masjid Sepahsalar, Tehran)

The *Tanqih al-Manazir* would become widely spread in the Muslim world, where it was used in academic classrooms, and would be commented upon until the sixteenth century. Therefore, in the Muslim world, this would be the main textbook on optics for more than three centuries. Since it would never be translated into any Western language, its influence on European science would remain marginal at best.

Al-Haytham (Alhazen), Abū 'Alī al-Ḥasan ibn al-Ḥasan ibn

Eric Kirchner

Kirchner Publications, Leiden, The Netherlands

Abu Ali al-Hasan Ibn al-Haytham (Latinized name: Alhazen) made important discoveries in astronomy, mathematics, and optics. His *Kitab al-Manazir* (Book on Optics) made the works of Aristotle, Ptolemy, and Euclid obsolete. He merged their classical theories, combining the mathematical, physical, and physiological aspects into one unified optical theory. The *Kitab al-Manazir* also introduced the distinction between optics and physiology/psychology that is a cornerstone of modern optics and colorimetry.

In his work, Ibn al-Haytham attempted to show how illumination, hue, and saturation combine together into color perception. Although he was not able to establish a complete system of color attributes, his account is largely consistent. “In terms of scope, details and comprehensiveness of treatment, Ibn al-Haytham's observations on the subject of color perception are unequalled in

any single writer before him” (Vol. 2, p. 43 in Ref. [1]).

The *Kitab al-Manazir* would be the dominant text on optics for several centuries to come, both in the East and West. Latin translations appeared from 1200 to 1572 (*Perspectiva, De aspectibus, Opticae Thesaurus*) and in Italian around 1350 (*Prospettiva*). Basing themselves on what they read in this book, Kamal al-Din al-Farisi and Theodoric of Freiburg around 1300 discovered the correct explanation for the colors of the rainbow. It also made Kepler to formulate in 1604 the theory of the retinal image and Rudolph Snel van Royen to discover a few years later what is now known as Snellius’ law of refraction. In the East, Ibn al-Haytham’s work survived through its thorough treatment and further elaboration by Kamal al-Din al-Farisi (d. 1318).

Ibn al-Haytham was born around 965 AD in Basra (Iraq) where he became a famous mathematician. Caliph al-Hakim of Cairo, impressed by Ibn al-Haytham’s claim that he could regulate the flow of the Nile, persuaded him to come to Egypt. However, Ibn al-Haytham soon found out that he was not up to the task. He fell in disgrace and was placed under house arrest for many years. This proved to be beneficent for continuing his studies in mathematics, astronomy, and optics.

According to Aristotle, light was a manifestation of a change of the state of the medium from opaque to transparent. Ptolemy had considered vision to be the result of visual rays, spreading out from the eye that were reflected or refracted by surfaces of objects. Ibn al-Haytham (as well as Ibn Rushd) proposed an alternative view, that light has a much more active role in color vision. It is light which is seen, according to Ibn al-Haytham [2]. Moreover, light is directed toward the eye instead of spreading from it. Ibn al-Haytham was the first to consider light as an entity by itself, traveling from visible objects to the eye, according to mathematical laws originally proposed by Euclid [3]. Regarding the role of the medium for color vision, Ibn al-Haytham adopted the view from al-Kindi (d. 873) that the medium plays a passive role in color vision in the sense that it should not block vision.

In Ibn al-Haytham’s theory, color is a distinct property of material bodies. He stated that color

and light are distinct but that colors behave exactly as light does in transmission, reflectance, and refraction. Therefore, Ibn al-Haytham’s theory of light is at the same time a theory of color [4]. But apart from formulating these theories, Ibn al-Haytham went further and designed many experiments by which he verified the proposal step by step and afterward subjected the results to thorough mathematical analysis [5] (and also Vol. 2, p. xli in Ref. [1]). Nevertheless, Ibn al-Haytham also explored some more philosophical treatments of color and light [5].

Ibn al-Haytham’s view of the active role of light in color vision made him investigate many crucial aspects of color vision. He described how changing the type and intensity of light affects the color appearance of objects and how a stronger light intensity increased perceived color differences [6, 7]. Thus Ibn al-Haytham came close to what has been called a key notion in colorimetry that color is the product of the eye, the light, and the object. In the words of Ibn al-Haytham: “This behavior indicates that the eye observes the colors of colored objects only according to the colors that fall on them” [6, 7].

Ibn al-Haytham was one of the first to use the word saturation as describing an aspect of color. Ibn al-Haytham used this word in his *Kitab al-Manazir*. Generally it refers to the sensation one feels after a copious meal, indeed analogous to the modern English word saturation. In modern Arabic, the same word is still used for color saturation [8]. About this and other words related to color that appear in the *Kitab al-Manazir*, see Vol. 2, p. 43 in Ref. [1].

In other aspects, Ibn al-Haytham followed the classical traditions. He supported the Aristotelian view that the colors of the rainbow are the result of mixing light and darkness and the Ptolemaic interpretation that color mixing in the spinning top is a visual illusion.

Alizarin

Tuane Cristina dos Santos
North Carolina State University, Raleigh,
NC, USA

Synonyms

1,2-Dihydroxy-9,10-anthracenedione; 1,2-Dihydroxyanthraquinone; Alizarin red; Alizarine; CI Mordant red 11; Madder lake; Turkey red

Definition

Alizarin is a redish-orange anthraquinone dye with formula $C_{14}H_8O_4$. It can be extracted from the roots of plants of the madder genus or be obtained synthetically. Historically, it has been used for dyeing textiles.

Overview

Alizarin (1,2-dihydroxyanthraquinone) is normally the main colorant extracted from the dried roots of the plant *Rubia tinctorum* L (Madder) and is undoubtedly the best known of the anthraquinone natural dyes. Its chemical formula is shown in Fig. 1. Madder has been used as a dye source for many centuries, being cultivated in central

Alizarin, Fig. 1 Structure of alizarin

Asia and Egypt, where it was grown as early as 1500 BC. In 1826, alizarin was first isolated from madder roots by the chemist Pierre-Jean Robiquet who found two colorants in the madder root extract: the red dye alizarin (~4% by weight) and the more rapidly fading dye purpurin [1]. The 1865 discovery of the chemical constitution of benzene opened the door to the elucidation of the molecular structure of alizarin by Graebe and Liebermann in 1867 and to synthetic approaches to this interesting natural colorant. Thus, anthraquinone dyes as a family of industrial compounds can trace their roots back to the determination of alizarin's structure.

In 1868, alizarin became the first natural dye component produced synthetically [2]. Its initial synthesis involved a two-step sequence from anthraquinone, namely bromination and hydroxylation, as illustrated in Fig. 2. There it can be seen that bromination occurs in two of the beta positions (2,3-positions) but fusion with alkali in the second step produces 1,2-dihydroxyanthraquinone (alizarin; **A**) rather than the 2,3-dihydroxyanthraquinone isomer (**B**) [3]. The cost of bromine and practical difficulties associated with scale-up prevented commercialization of this approach. It was later determined that the synthesis of alizarin from anthraquinone-2-sulfonic acid was commercially viable and the method of choice. The principal synthesis route involved the conversion of anthraquinone-2-sodium sulfonate ("silver salt") to 2-hydroxyanthraquinone using hot KOH and oxidation with sodium nitrate or sodium chlorate in alkaline media to give alizarin [4]. Thus, this process not only gave the expected replacement of SO_3Na by OH but also introduced an OH group in the 1-position [5]. An overview of a proposed reaction mechanism for the series of addition and elimination steps leading to alizarin is given

Alizarin, Fig. 2 Early synthesis of alizarin

Alizarin, Fig. 3 Steps in the commercial synthesis of alizarin

in Fig. 3. Step 1 starts with anthraquinone-2-sulfonate (C) and is the first of two hydroxide (OH^-) addition steps. This is followed by the loss of a proton (Step 2) and air oxidation (Step 3), to give 1-hydroxyanthraquinone-2-sulfonate (D). The second addition of OH^- (Step 4) is accompanied by elimination of sulfite (SO_3^{2-}) (Step 5) to give alizarin [6, 7]. Synthetic alizarin became very appealing, as it was cheaper and did not require the laborious extraction of the colorant from the plant material [8]. These advantages virtually eliminated the market for natural madder, ending the presence of huge cultivations in parts of Europe that dated back to 1800. Subsequently, however, natural madder could be obtained from Africa and South America [9].

Alizarin is slightly soluble in water but readily soluble in alcohol, ether, and alkaline solutions. Natural alizarin can be used as a pH indicator, as its color varies from scarlet to pink to red with a bluish tint depending on the strength of alkali or acid used. Strong alkali produces a violet-blue color, while a strong acid gives yellowish-red [1].

Other applications include its use as a food colorant, in cosmetics, and in textile dyeing [10]. Regarding its textile use, alizarin is classified as a mordant dye (CI Mordant Red 11), since it readily forms a dye-metal complex on fibers, notably when using aluminum ions (Al^{3+}). Its complexes show more intense colors and an enhanced set of fastness properties (stability under end-use conditions) compared with the parent (uncomplexed)

dye. In the actual dyeing process, mordant and dye combine to form a less soluble colorant within the textile fibers, which makes the dyed fiber resistant to external influences such as washing and finishing processes [11]. Furthermore, the choice of mordants used influences the final shade obtained. For example, pink can be obtained when alizarin complexes with tin, violet when it complexes with iron, and red upon complexing with aluminum, especially on leather and cotton [12]. In the brown trivalent chromium–alizarin complex, the chromium ion is coordinated with three bidentate alizarin molecules [13]. In turn, this complex bonds to protein-based fibers (wool and silk) through the formation of hydrogen bonds between the polypeptide linkages and the dye [9]. Nowadays, alizarin is mostly used as a staining agent in biochemical assays and in water-color and oil painting.

Although natural dyes are generally considered to be eco-friendly, since they are mainly derived from plants and other renewable sources, their production, mode of application to fibers (use of metallic mordants), mode of action in the human body, and environmental fate are not completely free from concerns [14]. With this in mind, studies concerning the carcinogenic and mutagenic potential of madder extract and alizarin have been conducted. Madder-related studies performed in rats showed chronic toxicity targeting kidney, liver, and blood cells [15], and both renal tubule cell and hepatic carcinogenicity [16]. Moreover, madder was mutagenic to strains TA100 and TA98 of *Salmonella typhimurium*, with the observed mutagenicity attributed to components present in the madder root extracts other than alizarin [17]. However, in another study, alizarin was strongly mutagenic to strain TA2637 with metabolic activation [18].

In medicinal studies, natural alizarin has been shown to have antitumor properties (in colon cancer cells) and low dosages exhibited selective inhibition of osteosarcoma and breast carcinoma cell proliferation in in vitro studies [19]. Alizarin has also exhibited antifungal properties, with the potential to be used in the treatment of candidiasis [20].

Al-Tusi, Nasir al-Din

Eric Kirchner¹ and Seyed Hossein Amirshahi²

¹Kirchner Publications, Leiden, The Netherlands

²AUT Textile Department, Amirkabir University of Technology, Tehran Polytechnic, Tehran, Iran

Muhammad ibn Muhammad ibn Hasan al-Tusi, usually known as Nasir al-Din al-Tusi, was born in Tus (Iran) and later worked in Maragha (Azerbaijani) and Baghdad (Iraq). His influence

reaches into many fields [1]. His work on reforming Ptolemaic theoretical astronomy would be crucial for later astronomers, including Copernicus. In mathematics he published landmark editions of the works of Euclid and Archimedes and developed trigonometry as a discipline separated from astronomy. He wrote several works on optics [2]. For Shiite theology, al-Tusi wrote an important work on ethics, and he also authored the first systematic treatment of rationalist theology in 12 imam Shiism, a work still central in Shiite theological education.

Al-Tusi was born in a Twelver Shi'a family. Under patrons at Ismaili courts, he became a famous mathematician. When in 1256 under Mongol rule, Hulagu destroyed the Abbasid Empire, al-Tusi had taken refuge at the last Ismaili stronghold located on the mount of Alamut. After the Mongols destroyed this mountain fortress, Hulagu personally saved al-Tusi's life since the ruler's interest in astrology made him respect al-Tusi's astronomical knowledge. Al-Tusi persuaded Hulagu to support building the first full-scale astronomical observatory in the world at Maragha. With al-Tusi as director, it would collect a mass of observation data during about 50 years, and it would inspire later observatories in Samarkand and India and possibly even Tycho Brahe's observatory in Denmark.

Al-Tusi thoroughly studied the works of Ibn Sina. When after teaching Ibn Sina's color theory one of his students wanted to know more about it, al-Tusi replied in a letter:

Regarding the production of colors from black and white there are numerous paths, from which one gradually walks from white to black. The path through yellow belongs there: First by the mixing of dense and fire, both in small amount, the straw-yellow is produced, then the lemon-yellow, then the saffron-yellow, then the orange-yellow, then the grenade-yellow, then in it the tendency towards black increases, according to the increase in the number of dense particles and the decrease of fire, until it becomes black.

Another path goes through red. First it becomes rosy, then like evening-red, then blood-colored, then purple, then violet, violet-colored. [...]

This all occurs according to the differences of particles in transparency, opacity (density), light and darkness. Now and then one sees a color together with another, and a different color is

produced, such as green from yellow and blue, verdigris from green and white. There are infinitely many of such arrangements, and some are often found in small particles of plants and animals. Anyone who observes them is surprised by their number. [3, 4]

Thus, while Ibn Sina had specified three paths from white to black, al-Tusi described five of such paths. They go via yellow, red, green, blue, and gray, *as illustrated in the Figure above*. Remarkably Forsius in 1611 also described five different tint/shade scales from white to black. This may all be compared to the German monk Theophilus (ca. 1120), who described how to produce up to 12 grades in a tint/shade scale. The text of al-Tusi shows that he must have considered color space to be two dimensional. Interestingly, at approximately the same time in Latin Europe, Grosseteste had argued on theoretical grounds that color space is three dimensional [5, 6].

Also in his work on minerals and gem stones, the *Tansukhname-yi Ilkhani* (the book on precious stones for the Ilkhan [i.e., for Mongol ruler Hulagu]), al-Tusi describes a color theory [3, 7]. Written primarily by Nishaburi, and largely copied by al-Tusi and Kashani, these texts are the first to describe a limited hue scale. It describes that by mixing blue and yellow in different proportions, colors are produced that change gradually from blue, via green, to yellow. This description represents a great step forward from the Aristotelian point of view that stated that green is one of the colors painters cannot produce. Although several scholars before Nishaburi and al-Tusi had mentioned that green can be produced by mixing blue and yellow, no earlier scholar had described that depending on the mixing ratios, different hues of green are produced [6].

The common opinion among scholars since Aristotle had been that by mixing black and white all colors can be produced. But following Nishaburi, Tusi wrote that “if white color and black color are mixed with each other, an incense-grey color will result.” This had been stated only twice before in history and in much less clear wordings. Clearly this statement, which was a starting point for Newton’s optical work, was not made for the first time by Scaliger in 1557, as is generally thought [8].

Anchoring Theory of Lightness

Alan Gilchrist

Department of Psychology, Rutgers University,
Newark, NJ, USA

Synonyms

Achromatic color; Perceived reflectance; Perceived value

Definition

Lightness refers to the white, black, or gray shade of a surface. The basic problem is that the light reaching the eye from a given surface, as the product of surface reflectance and illumination,

does not specify the reflectance of the surface. A black in sunlight can reflect more light than a white in shadow. No computer program exists that can identify the reflectance of an object in a photo or video. Any possible solution must exploit the context surrounding the object. Anchoring theory proposes to solve the problem by grouping patches of the retinal image into regions of equal illumination, called frameworks, then computing lightness values within each framework using rules of anchoring combined with luminance ratios.

Background

Lightness refers to the perceived shade of white, gray, or black of a surface and is sometimes called perceived reflectance. The reflectance of a surface is the percentage of light it reflects. White surfaces reflect about 90% of the light that illuminates them while black surfaces reflect only about 3%. Given the light-sensitive receptor cells in the eye, one might think that the perception of lightness could be easily explained. But the amount of light reflected by a surface, called luminance, depends not only on its reflectance but also on the intensity of light illuminating it. And the intensity of illumination varies from place to place and time to time. Thus, a black surface in sunlight can easily reflect more light than a white in shadow. In fact, any shade of gray can reflect any amount of light.

The ability to perceive the correct shade of gray of a surface despite variations (both spatial and temporal) in illumination is called lightness constancy, or more specifically, illumination-independent lightness constancy. The ability to perceive the correct shade of gray despite variations in the luminance of the background surrounding a target surface is called background-independent constancy. Neither type of constancy is complete. Variations in illumination level produce failures of constancy as described in the traditional literature, while variations in background produce failures of constancy that have been called contrast effects.

Summary of the Theory

According to anchoring theory [1], the lightness of a target surface is codetermined by its relationship to the field of illumination in which it is embedded, called the local framework, and its relationship to the entire visual field, or global framework. The values computed within these local and global frameworks are combined in a weighted average. Within each framework, the value is based on the ratio between the luminance of the target surface and the highest luminance in the framework, called the anchor. The weight of a framework depends on its size and complexity. Framework boundaries include corners, occlusion contours, and penumbrae.

Frameworks

Helmholtz [2] suggested that given the luminance of a target surface, the visual system would have to somehow take into account the intensity of light illuminating that surface in order to compute its reflectance. But in fact this is overkill. To compute lightness, the visual system needs to know only which surfaces are under *the same level of illumination*. In anchoring theory, each scene is perceptually segmented into regions of homogeneous illumination, as Koffka [3] suggested. Thus any luminance differences within each of these frames of reference must represent reflectance differences. By comparing only surfaces that are equally illuminated, reflectance and illumination are disentangled, not by estimating illumination but by holding it constant.

Frameworks are equivalent to perceptual groups, in which retinal patches are grouped by common illumination, a process that parallels the more traditional gestalt idea of grouping by which objects are segregated, which can be thought of as grouping by common reflectance.

Anchoring

In 1948, Wallach [4] proposed the idea that lightness depends simply on the ratio between the

luminance of a surface and the luminance of the surrounding region. There is clearly much validity in this proposal. A homogenous disk of constant luminance can be made to appear as any shade of gray from white to black simply by varying the luminance of a homogeneous ring that surrounds it. However, relative luminance per se can only produce relative shades of gray. For example, consider two adjacent surfaces whose luminance values stand in a 5:1 ratio. These could be white and middle gray. But they might also be light gray and dark gray, middle gray and black, or any number of reflectance pairs. To determine the specific shade of a surface requires, in addition to relative luminance, an anchoring rule – that is, a rule that links some value of relative luminance to some value on the gray scale. Anchoring theory invokes a highest luminance rule according to which the highest luminance within a region of illumination is perceived as white, and this value serves as the standard to which lower luminance values are compared.

Simple and Complex Images

Anchoring theory makes an important distinction between simple images and complex images. A simple image is one in which a single level of illumination fills the entire visual field while a complex image, typical of most images we see, contains multiple levels of illumination. The theory also describes how the rules for simple and complex images are related to each other.

Simple Images

In a simple image, the formula used to predict lightness value of a given target surface is **Lightness** = $T/H * 0.9$, where **T** is the luminance of the target, **H** is the highest luminance in the image, and **0.9** is the reflectance of white.

Geometric relationships, in addition to photometric relationships, also play a role in anchoring. Lightness depends, to a limited extent, on the relative area of surfaces. In general, lightness increases as relative area increases. But according

to anchoring theory, this effect of “the larger the lighter” applies only when that darker surface fills more than half of the area of the visual field.

Complex Images

While it is not hard to exhaust the rules by which lightness is computed in simple images, the more important goal of a theory of lightness is to explain how lightness is computed in complex images typical of the real world. Anchoring theory makes the claim that complex images are related to simple images according to two principles. The first is that the same rules of lightness computation found in simple images apply to frameworks embedded in complex images. The second involves a kind of crosstalk between frameworks called codetermination.

Codetermination

The term *codetermination* was coined by Kardos [5], a gestalt psychologist from Budapest. He proposed a friendly amendment to Koffka’s idea of frameworks, observing that the lightness of a target is not computed exclusively within its framework but is influenced by neighboring frameworks as well. Kardos argued that the lightness of a surface is partly determined by its relative luminance in the field of illumination to which it belongs, called the relevant field, and partly by its relationship to a neighboring field of illumination, which he called the foreign field.

Anchoring theory invokes the closely related concepts of local and global frameworks. The global framework is the entire visual field. Unlike relevant and foreign frameworks, which are exclusive, local and global frameworks are hierarchical. The local framework is nested within the global.

Segmentation and Grouping

Frameworks are the products of both segmentation and its inverse: grouping. Segmentation

factors include cast illumination edges, such as the border of a shadow or spotlight, corners, where the planarity of a surface changes, and occlusion boundaries, where one object partially obscures a more distant object. Such illumination boundaries effectively group retinal patches by illumination level.

Additional gestalt grouping factors are held to create weak frameworks. In the simultaneous lightness contrast illusion, for example, a gray patch on a white background appears slightly darker than the same gray patch on a black background. Although the black and white backgrounds are equally illuminated (and thus the two patches should have the same lightness value), each patch is perceptually grouped with its background due to adjacency and surroundedness and these weak frameworks cause the (weak) illusion.

Veridicality Versus Error

In general, theories of lightness have sought to account for lightness constancy, and the degree to which perceived lightness corresponds to physical reflectance. However, an adequate theory of lightness must also explain failures of constancy. The Kardos theory of codetermination was the first lightness theory to confront this problem. The failure of constancy within a relevant field is due to the unwanted influence of the foreign field. Anchoring theory endorses this construction but also broadens it to include a larger class of what can be called lightness errors. This class includes lightness illusions in addition to failures of constancy. Illusions and constancy failures have traditionally been treated separately but both constitute errors.

The most basic and familiar illusion of lightness is called simultaneous contrast. Two identical gray patches are placed, respectively, on adjacent black and white backgrounds. The patch on the black background appears lighter than the patch on the white background. The application of anchoring theory to this illusion is rather simple. The illusion is obviously composed of two frameworks, corresponding to the two backgrounds.

These two frameworks taken together can be considered the global framework. For each gray patch, both a local and a global value are computed. In the global framework, both gray patches are computed to be middle gray. But they get different values when computed locally. The patch on the black background is given a value of white in its local framework, because it is the highest luminance. However, the patch on the white background is computed to be middle gray, relative to its white surround. When the local and global values for each patch are combined in a weighted average, the patch on the black background ends up with a slightly higher value. According to anchoring theory, this “contrast effect” is relatively weak because the two local frameworks are weak, due to their lack of articulation.

According to anchoring theory, the simultaneous contrast illusion is not caused by lateral inhibition or any exaggeration of edge differences but rather by the fact that one patch is perceptually grouped with the black background while the other patch is grouped with the white background. Consistent with this grouping approach, several authors have produced reverse contrast illusions. These illusions are variations of simultaneous contrast in which a gray patch on the black background appears darker, not lighter, than an identical gray patch on the white background. This reversed effect is created by making the gray patch a member of a group of patches that are opposite in lightness from the black background. Thus, the gray patch on the black background is part of a matrix of white patches of the same size and shape. The gray patch on the white background is likewise part of a group of black patches. These reverse contrast illusions support the concept of grouping that is fundamental to gestalt theories in general and anchoring theory in particular.

Weighting

To implement the concept of codetermination, a provisional lightness value is computed for the target within each framework, including the

global, and then a weighted average of these values is computed. The weight of each framework in this average depends on the size of the framework and the degree of complexity within it.

The factors of framework size and articulation come from the early work of David Katz [6]. Having invented some of the fundamental methods for studying lightness, Katz conducted experiments testing the factors that lead to strong and weak constancy. He found that the degree of constancy varies in proportion to the size of a framework, which he called field size, and even more-so to its level of articulation, operationally defined simply as the number of distinct elements within it.

The concepts of field size and articulation are given a slightly different interpretation in anchoring theory. Rather than factors consistently leading to good constancy, they are treated as factors that determine the relative weight of a framework. Thus, for example, replacing the white and black backgrounds of the simultaneous contrast illusion by collages of light gray and dark gray patches, respectively, increases the weight of the two backgrounds and increases the size of the illusion. Constancy, that is, is reduced, not increased.

The general formula for a target surface belonging to the global framework and one local framework is:

$$\text{Lightness} = W(T/H_l * 0.9) + (1 - W_l) \times (T/H_g * 0.9).$$

in which **W** is the weight of the local framework, **T** is target luminance, **H_l** is the highest luminance in the local framework, **H_g** is the highest luminance in the global framework, and **0.9** is the reflectance of white.

Staircase Gelb Effect

Anchoring theory was inspired by an empirical finding called the staircase Gelb effect. Gelb had shown that a piece of black paper appears white when suspended in midair and illuminated by a spotlight. In the staircase version, a row of five squares arranged in an ascending series from

black to white is placed within the spotlight. This produces a dramatic compression of the perceived range of grays. Although the squares range from white to black, they appear to range only from white to a light middle gray, a phenomenon now known as gamut compression.

This finding seriously undermined several earlier decomposition theories of lightness but suggested an interaction between the bright illumination on the five squares and the dimmer illumination of the room. According to anchoring theory, each of the squares is assigned its correct value within the local spotlight framework. But relative to the surrounding room, as long as the spotlight is at least 30 times brighter than the illumination level in the room, each square is assigned the same (global) value of white, given that its luminance is as high as, or higher than, a white surface in the room light. The perceived compression of the lightness range is explained by these equal values assigned to the squares relative to the room illumination.

The Scaling Problem

The mapping of luminance values onto lightness values within a given framework involves both anchoring and scaling. If anchoring concerns which *value* of relative luminance is linked to which *value* of lightness, scaling concerns which *range* of luminance values is linked to which *range* of lightness values. Much as a normal distribution can be characterized by both a measure of central tendency and a measure of dispersion, so a set of luminance values within a framework can be converted to lightness values using an anchoring rule and a scaling coefficient (although the anchor is located at the top, rather than in the center, of the range).

Wallach's ratio principle assumes a one-to-one scaling coefficient. That is, if the luminance ratio between two adjacent surfaces is 3:1, then the ratio of their two perceived reflectance values must also be 3:1. This scaling metric is implicit in the formula given above: **Lightness = T/H * 0.9**. It can be considered the default scaling metric

and applies to large, well-articulated frameworks typical of everyday scenes.

In the staircase Gelb illusion, the range of perceived values in the spotlight is compressed due to the presence of the lower illumination surrounding the spotlight. However, within each framework, the perceived range can be either compressed or expanded, based on its actual range. The theory includes a scale normalization principle, according to which the range of perceived lightness values tends toward the canonical 30:1 white–black range (from 90% to 3%). When the luminance range within a framework is less than 30:1, the lightness range is expanded, and when the luminance range exceeds 30:1, the lightness range is compressed. The degree of expansion or compression is proportional to the deviation of the range from 30:1, but the normalization is only partial.

Anchoring in Other Domains

The anchoring problem arises in other perceptual domains including perceived size and perceived motion. Motion is a good example. There is a good deal of evidence that perceived motion depends on relative motion, but to achieve specific values of motion, relative motion must be anchored. Here, the metaphor of an anchor is even more intuitive than in lightness. In a matrix of relative motions, which elements will be perceived as stationary? In his brilliant writing on perceived motion, Duncker [7] stressed the importance of frames of reference. And he talked specifically about anchoring rules in a way that appears highly consistent with the anchoring theory of lightness.

Strengths and Weaknesses of the Theory

Anchoring theory has wide applicability within lightness perception. It is consistent with an extensive range of empirical data. In general, it accounts for veridical perception to the degree

that perceived lightness is veridical. But unlike most other theories, it also accounts for a wide range of known lightness errors, that is, lightness illusions and failures of constancy. This is important because the pattern of errors shown by humans in lightness perception must be the signature of our visual software.

But anchoring theory remains a work in progress. Recent empirical work appears to require several modifications of the theory, including these:

1. The concepts of nested local and global frameworks should be replaced by the Kardos concepts of relevant and foreign frameworks.
2. New work suggests that the concept of code-termination is implemented, not by averaging the local and global values for each square separately, but by the assignment of an anchor and a scaling coefficient to each framework. Both the anchor and the scaling coefficient are codetermined by the foreign framework and the relevant framework.

These changes provide a more satisfactory account of the staircase Gelb illusion. For a framework of one illumination level surrounded by a region of different illumination, the degree of gamut compression has been shown to correlate with the ratio between the highest luminance values in the two frameworks. But these changes complicate the explanation of simultaneous lightness contrast, for which the original version of the theory was very effective.

Definition

Color terms or partitions of color denotata evidenced in ancient language artifacts.

Words and Hues, Languages and Time: An Overview

The sources for understanding the earliest color terms and categories are from the lands around the

eastern Mediterranean Sea, beginning some 5000 years ago. Evidence of color categories from Proto-Cuneiform, Sumerian, Egyptian, and Akkadian (i.e., Babylonian) in Mesopotamia and Egypt (from the end of the fourth millennium BC onward) is followed (from the second half of the second millennium onward) by (Mycenaean) Greek in the West and (Archaic) Chinese in the East. Mesoamerican Maya can be traced back to roots in the first millennium BC, but color is only attested from the first and second millennia AD. Egyptian is the only language which can be traced back from the third millennium BC down to the first millennium AD, meaning that it is the longest lasting of the early languages – and reveals major changes. Maya is much later and the terminology is historically consistent over a long period. As a group, the words discussed here represent six or seven different linguistic families (Sumerian, Afro-Asiatic, Semitic, Indo-European, Sino-Tibetan, and Mayan; the affiliation of Proto-Cuneiform is disputed), with linguistic terms relating to some fundamental colors (dark/black, bright/white, red) with other terms (reds, greens, blues, and yellows) present to some degree in most of these languages.

What is known about the earliest color categories is derived from artifacts and texts. The use of color can be traced back more 300,000 years, but the origins of color vocabulary probably lie in the period since roughly 8000 BC (=10,000 years ago); the earliest texts (from ca. 3500 BC in Mesopotamia) appear millennia later, with color only appearing in a relevant fashion after 3000 BC. By comparison with the languages discussed here, virtually all other languages with complex color vocabularies are either much younger (e.g., Hebrew, Latin), or contemporary (e.g., Eblaitic, Hittite, Ugaritic), and all are linguistically related to the languages discussed here.

Vocabularies in the earliest preserved languages offer representative and definitive evidence concerning the origins of color categorization and its linguistic expression, as well as allowing evaluations of different steps in the process of abstraction and the early linguistic partitioning of perceptual color space.

(For linguistic and historical details, see [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 20, 21]). Before Plato – in Classical Greece (which in the mid-first millennium BC is relatively late for the discourse in this entry) – no thinkers left traces of discussions about color, and thus all of our interpretations about colors from the second and third millennia BC are based on modern interpretations of evidence and not ancient commentaries.

Color Terminology

Black and White, Bright and Dark

The earliest color lexicons from languages of the Middle East and the eastern Mediterranean (Proto-Cuneiform, Sumerian, Akkadian, Egyptian, and early Greek) have words signifying “dark” and “light”; some of these terms also denote something closer to “black” or “white”; and some are related to materials. Egyptian and Sumerian “white” are linked to silver, with the Sumerian also related to “purity,” suggesting that white as a distinct color was added to color vocabulary in historical times. There were usually several terms, as, e.g., Mycenaean Greek *re-u-ko* (the antecedent of Classical Greek *leukós*, “bright,” “white”) was accompanied by *pa-ra-ko*, apparently a white pigment used for dying (Classical *barakis*) – but also used figuratively for a color. Objectively, we can simply confirm that, like most of the more specific terms for “black” in most ancient languages, even Classical Greek *mélas* had a semantic range including “black” and “dark” [16] that encompassed some regions described in English as “brown” – which Schenkel also suggests for ancient Egyptian “black,” *km* (in [12]), and this can be assumed for Sumerian *gege* (meaning “black” and “dark” in Sumerian, and probably appearing in Egyptian as *kk.w* a loan-word meaning only “[extreme] darkness,” “blackness”).

While words for “white” could include “bright,” and those for “black” could include “dark,” these words remained distinct from other words meaning vaguely “bright” or “dark.”

Red

All of the ancient languages have words for some color(s) in the red range. Red ocher was also the first pigment used by humans, hundreds of thousands of years ago, but the word is probably unknown. Unless, the continuity discussed below – from Akkadian *ruššu* “red” to Italian *rosso* – might mean that the English word “red” (like German *rot*) is a direct successor of the earliest word for red, invented relatively recently, but still thousands of years ago (and perhaps before “white”). The Mycenaean Greek Linear B *e-ru-to-ro* is doubtless the same word, and leads into Classical Greek *eruthrós*. Yet *eruthrós* was not the primary word for “red” in second millennium Greek, as there were others, the most important being *po-ni-ko-ro*, a loanword, later *phoîniks*, related to “purple,” “crimson,” and “Phoenician” (parallel to the much rarer Mycenaean *po-pu-re-ja*, later *porphúreos*, a different loan word, used in Classical Greek). Likewise, the most important “red” in Akkadian was not *ruššu*, but *sāmu*, related to *sāmtu*, “red carnelian.” Schenkel has argued for *dšr*, *tjms*, and *mroš* all designating different “reds” in Egyptian. Chinese *hóng* was a pink before becoming a “red,” replacing *chì* (which was earlier red). Red was clearly identified as a color range by the third millennium, but the terminology was unstable. All ancient languages exhibit a very clear tendency for a division of the reddish continuum of color experiences into several different terms related to hues, with loanwords and materials playing a key role in the development of the red category. The modern concept of a “red” category was the result of fusing the various reds into a single group.

Green, Green-Blue, and Green-Yellow

The Egyptian (*wādj*) and Akkadian (*warqu*) color terms that denote what today is referred to as “green” in English are derived from the same linguistic root but do not invariably denote the same color: the Sumerian *sig* is equivalent to Akkadian *warqu* and both also designate “yellow” (as in vegetation having both shades, but not in the sense of a green-yellow); the focus of Egyptian *wādj* is definitely in the “green” range (and not in

the green-blue range as originally suspected, cf. Schenkel in [1, 2, 12]).

There was no generic word for what is today understood as “green” in Greek, although *xlōros* eventually came to mean something like “green”; however, the earliest use of color terms in Greek was not specific – or rather green was divided among a number of words, and not dominated by a “green-blue.”

qīng (青) – a Chinese term meaning “blue,” “green,” and “black,” but neither “dark” nor “green-blue” (with, however, a homonym including an additional radical [*qīng* 清] meaning “clear”!) – has not yet been found in the earliest Chinese inscriptions. Since the first millennium BC, *qīng* is used for “green,” “blue,” and “black”; only slightly later the word *lǜ*, today’s “green,” also appeared, so that in Chinese to some extent “green” has since been divided into “light” and “dark” green [5]. There is a still current old expression using the two different words for “green”: *qīng shān, lǜ shuǐ*; when translated narrowly, it would be “green mountains and green waters,” but actually means “(dark) green hills and (light) green lakes.” This phrase confirms an early and prolonged verbal division of the green part of the spectrum (Fig. 1).

Green clearly was not linguistically demarcated in a clear fashion with a unique term in any of the earliest languages except Egyptian – where its focus was in green as the spectrum is customarily divided, and not fused with other hues (Schenkel in [2, 12]). Otherwise, words for “green” designated not a vague color range, but rather distinct hues, i.e., in Mesopotamia “yellow” and “green,” in China “blue” and “green” – and **not** “green-blue” **nor** “green-yellow”; **nor** a general “dark.”

Yellow

Early evidence of terms glossing “yellow” is not common. In Egyptian, linguistic use of the word for “gold” (*nb.w*) for “yellow” began in the early third millennium BC, but remained uncommon; in Egyptian painting, however, the color yellow was frequently used to depict what was intended to represent gold where required and also the sun on occasion [8]. To what extent the Egyptian

Ancient Color Terminology, Fig. 1 An image of southern China illustrating linguistic usage: 青山水色的天空 *qīng shān lǜ shuǐ lán sè de tiānkōng*; “dark green mountains, light green waters, the blue color of the heavenly vault.” *qīng* can also mean “blue” – as *ao*, the equivalent does in Japan today. Chinese has a highly differentiated vocabulary for green and blue, and the nuances reflect origins in the Bronze Age, but the abstraction and the distinction of hues is that of the era since the first millennium BC

“red”, *dšr*, was consciously used for “yellow” is not clear (Schenkel in [12]). The usage of gold in Akkadian texts with the meaning of “yellow” is even rarer than in Egyptian, and when used took the form of a simile; since the third millennium, Akkadian *duxšu* might have designated “yellow” taking the hue from calcite (Thavapalan in [12, 13]) (Fig. 2).

Although documented relatively early on in Chinese, it is unclear when *huáng* became a true color word meaning “yellow” (including “brown”); in antiquity, it was mixed with homonyms related to “royalty” and “jade” and thereby to “bright,” “brilliant,” as well as the color “yellow.” Chinese *jīn* (literally “gold”) seems to have been used for “yellow” from early on ([5, 18]), but not exclusively.

The later Greek words based on *xrusós*, “gold,” were frequently used to designate a color which was most probably “yellow.” Significantly,

Ancient Color Terminology, Fig. 2 Probably one of the oldest sentences formulated in writing in Ancient Egypt (at least decades before ca. 2600 BC), on a seal impression with the sun-god designated as *nbwj*, the “Golden One” (highlighted in the copy for readers: N.B. the original

impression was just mud; although the seal itself could have been made of lapis lazuli, there was no color in the impression, where the characters simply appeared as low relief in the mud), an early case of the use of “gold” for a yellow as a color term [17]

Mycenaean Greek Linear B and Classical Greek have two different words for a “yellow,” *ka-sa-to/ksanthós* and *ko-so-u-to/ksoûthos*, but neither is a real “yellow” [4], as the latter is presumably a yellow with a tinge of orange or red (as in saffron), and there is reason to suspect that *ko-so-u-to* (used to describe the colors of animal hides in Mycenaean Greek) might be closer to a “golden yellow” [16] or “brown,” depending upon context.

Blue

Blue is relatively well represented in most ancient languages – but not easily separable from materials (whether minerals, glass, or dyed textiles). In Akkadian (*uqnû*) and Egyptian (*xsbdj*), terms for lapis lazuli designated “dark blue” (both being loanwords related to the material, but derived from different words derived from some other languages). In Classical Greek, a term (*kuáneos*) for blue appearances is derived from the Mycenaean Greek Linear B *ku-wa-no*, a loan word apparently derived via Hittite *ku(wa)nnaš* and/or Ugaritic *iqnu* textually originally from the Akkadian *uqnû* (itself, however, a loanword of unknown origin). Akkadian used several other terms for blue, including *takiltu* (also known from Hebrew *tēkēlet*) for a more purple blue dye, and *xašmanum* for a “light blue” dye (from the Egyptian word for amethyst, *ḥsmn*, which was not used as a color word in Egyptian). In Egyptian,

turquoise (*mfkāt*) denoted “light blue.” Chinese *lán* is a term for “blue” color but appears quite late (in comparison to, e.g., Chinese “red,” “white,” “black,” “yellow”); *qīng* is also used for blue.

As a category, the modern English term “blue” evolved to ultimately eclipse the distinction established during early Antiquity (and still preserved in Russian) between light and dark blue.

Pink

Chinese is the only ancient language where one can be certain that *hóng*, a word that later came to mean “red” (the word used today) originally meant “pink” [18]. It is possible that Egyptian *dšr*, used here under “red” (as is the usual understanding), also included or meant “pink” (as it was always written with the flamingo ).

Table 1 offers an impression of what can be identified in the way of colors in these earliest languages.

Other Colors

Other colors are not clearly identified (or not hitherto recognized) in the earliest languages: the sweep of “yellow” could have included “brown”; the range of the “reds” will include “orange,” and “white” will include “gray.” Akkadian *makrû* – usually understood as a “red” – might mean “orange” on occasion. Probably

influenced by materials, shades distinguished within green, red, yellow, and blue were regarded as distinct colors, before the addition of additional colors.

Theory of Ancient Color Term Emergence

Debate regarding the sequence of the emergence of color in early color terminology is constrained by color term emergence theories (see also Encyclopedia of Color Science and Technology entry on ► [“Berlin and Kay Theory”](#)) using contemporary and recent language data to project modern color term emergence backward into history, rather than following the path forward, using the relevant ancient data discussed here.

Of extreme importance is that in ancient Egypt, the sun is occasionally called “red” and painted as such. This does not imply a “red-yellow,” but rather the use of a single term to designate what in modern languages are treated as different colors. The same goes for the Mesopotamian *warqu* “green” used for “yellow” and “green” as well as the Chinese *qīng* meaning “blue” and “green.” The reasons behind this do not lie in perception so much as expression.

That the Chinese had a “pink” before they had a red is but the tip of the iceberg (since “pink” should come much later according to Berlin & Kay). Most important is that “bright”/“white” and “dark”/“black” were not necessarily distinguished as color terms before the emergence of a “red.” Equally important is that before adding words for “brown,” “orange,” etc., the ancient languages divided “blue,” “red,” and “yellow,” with several different terms – with particularly disconcerting results for the value of “green.”

In later Western languages, “black,” “white,” “red,” “green,” “yellow,” and “blue” were each largely consolidated under one single word – as Berlin & Kay stipulate and in contrast to the earlier system where early languages had multiple “reds,” as exemplified in Schenkel’s work indisputably confirming the two or three reds in Egyptian before the acquisition of other colors.

Furthermore, there is less coherence when arguing abstraction, as this is less evident in the earliest languages where materials play a major role (see also Encyclopedia of Color Science and Technology entries on ► [“Materials and the Origins of Abstract Color Naming”](#); ► [“Evolution of Color Expression”](#)). This development of abstraction seems to have begun in parallel in both Chinese and Greek in the middle of the first millennium BC – but in neither of the ancient forms of these languages was any kind of systematic vocabulary developed that corresponds to the modern understanding of “green” or “blue.” Although – exceptionally – in both Chinese and Greek, “black,” “white,” and “red” seem to have been largely accommodated with suitable salient terms by the end of the first millennium BC, really adequate salient words for “yellow,” “blue,” and “green” did not emerge so clearly.

Warburton [7] argues that the earliest acquisition sequence was not an issue related to individual specific languages, but rather a shared phenomenon based on shared terminology, concepts, and materials. In this scheme, “ocher” (as dark red) will have been the earliest color used (in the Paleolithic, hundreds of thousands of years ago), followed by “greenstones” (in the earliest Neolithic, from 10,000 years ago), and “gold,” “silver,” “lapis lazuli,” “carnelian,” and “obsidian” (in the following late Neolithic and earliest Bronze Age) and then by turquoise (before 4500 years ago), amethyst, and other stones. The imitations in glass and faience bore the names of the stones, but they will hardly have consistently reproduced the hues recognized in languages today; dying textiles will have contributed yet more hues associated with specific terms – not all of which designated what would today be viewed as comparable colors. Initially, this led to a variety of color terms. “Black” and “white” may not have emerged from words for “dark” and “bright” before “red,” but rather linguistically crystallized as individual words after the understanding of “red,” probably the first linguistically distinct independent color recognized. Colors such as “pink” (in Chinese) and “orange” (in Akkadian, Egyptian, and Mycenaean) may have been recognized and designated with

Ancient Color Terminology, Fig. 3 Beads of gold, amethyst, carnelian, faience, and glass imitation of amethyst found in Crete at the end of the Minoan period (mid-second millennium BC [19]). Precious materials

specific names, but what they specified may be foreign to modern observers (Fig. 3).

Summary

Two of the three earliest linguistically recognized colors – “red,” “black,” “white” – may have been derived from materials of the ordinary existing world (perhaps ocher and soot), but the link between “white,” “silver,” and “purity” means that in linguistic terms, the third color already took us into the domain of precious materials. Henceforth, “precious materials” played an important role in the development of the advanced abstract color terminology (with stones of green, yellow, and blue along with gold), but with carnelian “red,” a precious material was intimately associated with a designation for a the shade of red already recognized earlier (ocher), splitting “red” and linking the perception and expression of color to hard, bright objects with intense clear hues all bound to materials and loanwords accompanying objects before, during, and after the period of the earliest recorded languages. The earliest recorded languages – Proto-Cuneiform, Sumerian, Egyptian, and Akkadian – reveal virtually no purely abstract colors with a focus on a recognizable color, but the art reveals a search for both pure reds, whites, and blacks while linguistically and artistically distinguishing different reds, blues, and greens. Abstract words appear

were traded and the names of faience and glass imitations adopted from the names of real precious stones, and used to designate textile dyes, bringing loanwords associated with strong hues into circulation

gradually in Chinese and Greek in the first millennium BC. Warburton suggests that the materials dominated and that the concept of abstract color terminology never developed in the Ancient Near East; yet the flow of loanwords meant that abstract terminology may have already been embryonic in the Aegean by ca. 1400 BC [8].

There is a clear difference between the descriptive uses of color in literature and economic texts. Although the sources are not balanced, there is little evidence of color from the earliest administrative texts in proto-cuneiform whereas color terminology appears in the administrative texts written from the third millennium onward.

Loanwords and shared etymologies play important roles in the emergence of ancient color terms in that many of the earliest words are related to designations of materials. Terms for “white” and “black” do not stand at the origins, and the red, blue, and green ranges were partitioned before being lumped together. Only later did the further color words begin to crystallize (in the last two millennia). The concept of “blue-green” is not documented in the earliest languages and does not really evoke any consistent color significance among potentially relevant living sources [5] suggesting that the concept may never have existed.

Since the third millennium BC, there has clearly been a gradual increase in understanding colors as hues and associating specific terms with specific parts of the spectrum. Even the simplest

color vocabulary is a very recent cognitive development: the use of complex abstract color language can hardly be extended back 5000 years [14], being instead an historical development in relatively recent millennia, leading to the emergence of abstraction in recent historical times. The Greeks acquired color concepts and terminology from the Near East through the diffusion of materials, ideas, and terminology. Their vague abstract ideas influenced the color lexicons of more recent languages.

Apparent Magnitude, Astronomy

Ken Tapping
D.R.A.O, National Research Council Canada,
Penticton, BC, Canada

Synonyms

Apparent magnitude – visual magnitude; Opacity – extinction

Definition

The apparent magnitude of a celestial object is a measure of how it looks to the eye. However, to make such a measurement useful to other observers at other locations and other times a more rigorous and transferrable standard is needed. This system needs to accommodate the different colors of celestial objects and the widely varying color sensitivity of the human eye. To achieve this, standardized systems of color filters have been established, which used together with standardized photometers, yield a useful system which not only defines the brightnesses of celestial objects in a consistent way, but also forms a useful basis for the spectral classification of stars.

Glossary of Terms

- Elevation: Angle between the geometrical horizon (as indicated by a spirit level) and the direction of the star or other object in question.
- Extinction: The degree to which starlight is weakened by the medium through which the light travels from the star to the observer. It is similar in meaning to “opacity” but is usually expressed in magnitudes. Zero means no extinction; otherwise the extinction indicates how many magnitudes fainter the object looks due to opacity of the interstellar medium and the atmosphere.

- Opacity: The degree to which light (or other optical radiation) is blocked when passing through the material in question. It varies between zero for something that is completely transparent and infinity for something completely opaque.
- Orthochromatic: This term refers to a type of photographic emulsion that was widely used in the earlier days of photography. It was very sensitive to blue and green light but insensitive to red light.
- Photometry: The measurement of quantities referred to light (visible optical radiation) as evaluated according to a given spectral luminous efficiency function (of the human eye). In astronomy, it applies to the measurement of the brightness of astronomical objects.
- Photosphere: The layer in a star’s atmosphere from which almost all of the heat and light are radiated. Because it lies at a fairly abrupt change in optical thickness, it looks almost like a solid surface and is often referred to colloquially as the “star’s surface.”
- Transmissivity: The fraction of the input energy passing through an attenuating device or layer. It varies from unity, for a completely transparent medium, to zero, for something completely opaque.
- Zenith angle: Angle between the local zenith and the direction in question.

Background

At the most fundamental level, the apparent magnitude of an object is a measure of how bright it looks. This is a function of the properties of the light source, its distance, the nature of the medium through which the light travels to the observer, and inevitably the properties of the observer or device used to make the measurement. When minimizing the subjective effects and trying to make the measurement more descriptive of the source and less related to the local circumstances of the observer, the parameter in question inevitably becomes less “apparent” but more useful. The history of “apparent magnitude” reflects such an evolution.

At a qualitative level, at a particular time and location, under the atmospheric conditions existing at that time, a specific observer can assess that some objects in the sky look brighter than others and possibly estimate by how much. This information may be useful to other observers present at the same location at the same time. However, recording such information for later consideration is difficult, and passing it in any usable form to another observer at another location for comparison of observations is even more so.

The development of the concept of “apparent magnitude” marks the beginning of an evolution toward producing quantities that are more intrinsic to the object being observed and can be combined with other observations. In the process, the term “apparent” becomes more a designator of a particular type of data rather than something literally true.

The flux from a distant star arriving at the top of the Earth’s atmosphere is given by

$$F_{00}(\lambda) = \alpha(\lambda) \frac{W^*(\lambda)}{4\pi R^2} \quad (1)$$

where W^* is the energy output of the star, R its distance from us, and α is the transmissivity of the interstellar medium along the path from the star to Earth. Note the wavelength dependence of these parameters. In this discussion, the “00” suffix identifies a quantity measured at the top of the Earth’s atmosphere.

Because the same value of F_{00} would be incidentally equal upon all points at the top of the Earth’s atmosphere, it would be common to all terrestrial observers. Therefore, in these discussions, F_{00} can be considered as the starting point.

In the development of the apparent magnitude concept, a number of issues arise. Firstly, since this is a comparative system, a defined calibration datum is required. In addition, starlight is not monochromatic; the atmosphere’s transmissivity (or opacity) varies with wavelength and so does the sensitivity of the detectors, sensors, or measurement devices used.

Quantifying Apparent Brightness

The concept of assigning “magnitudes” to stars was first proposed by the ancient Greeks, and has been attributed to Hipparchos [1], who was a Greek astronomer, geographer, and mathematician who lived about 190–120 BC. Accommodating the natural nonlinear response of our eyes to brightness, he assigned a magnitude scale where the brightest stars were categorized as being of the First Magnitude ($m = 1$), and the faintest stars visible to the unaided eye were defined as being of the Sixth Magnitude ($m = 6$), with each intervening magnitude corresponding to half the brightness of the next brighter class and twice the brightness of the next fainter. In this system, if the energy fluxes reaching from two stars of magnitude m_1 and m_2 are respectively F_1 and F_2 , the relationship between these quantities is

$$\frac{F_1}{F_2} = 2^{-(m_1 - m_2)} \quad (2)$$

This classification scheme for the apparent magnitude of stars was used for some time. Ptolemy used it in *The Almagest*, [2], his compendium of mathematical and astronomical information. Since the magnitudes as defined are exponents, taking logarithms of Eq. 2 puts it into a more convenient form

$$\begin{aligned} \log_{10} \left(\frac{F_1}{F_2} \right) &= -\log_{10}(2)(m_1 - m_2) \\ &= -(0.30102996 \dots) \\ &\quad \times (m_1 - m_2) \end{aligned} \quad (3)$$

so

$$(3.321928 \dots) \log_{10} \left(\frac{F_1}{F_2} \right) = -(m_1 - m_2) \quad (4)$$

The logarithm of the ratio of brightnesses is simply related to the magnitude difference. However having irrational numbers as the scaling factors is inconvenient, and in 1856, Norman Robert Pogson [3] redefined the magnitude scale in a more useful form. In Hipparchos’ system, a first

magnitude star is defined as being 64 times brighter than one of the sixth magnitude. Pogson changed the definition of the magnitude scale, defining a sixth magnitude star to be 100 times fainter than a first magnitude star. So the ratio of brightness between two adjacent magnitudes became

$$P = 100^{\frac{1}{5}} = 2.5118864315 \dots \quad (5)$$

This number has become known as *Pogson's Ratio* (P). Despite the apparent messiness of this number, it has an advantage in calculations. P is almost always used in the forms $\log_{10}(P)$ and $1/\log_{10}(P)$, which equal exactly 0.4 and 2.5, respectively. Thus, Eqs. 2 and 3 become

$$\frac{F_1}{F_2} = P^{-(m_1 - m_2)} \quad (6)$$

$$\begin{aligned} \therefore \log_{10}\left(\frac{F_1}{F_2}\right) &= -\log_{10}(P)(m_1 - m_2) \\ &= -0.4(m_1 - m_2) \end{aligned} \quad (7)$$

so

$$(m_1 - m_2) = -2.5 \log_{10}\left(\frac{F_1}{F_2}\right) \quad (8)$$

Since the magnitude system describes relative brightnesses, it needs to be based upon a calibration reference: a star to which a magnitude value has been assigned. Pogson first chose Polaris (also known as the Pole Star or North Star) as a calibrator, to which he assigned a magnitude of 2. However, when this star proved to be variable in brightness, he selected Vega, which he defined as having an apparent magnitude of 0. In practice, Vega is a better choice because it is available to observers over much of the world, and since it varies in elevation with time at any given site, other stars at similar elevations at that time can easily be set up as secondary or transfer calibration standards.

The nature of the magnitude scale makes it able to accommodate stars brighter than magnitude 0, which gives them negative magnitudes. For

example, Sirius, the brightest star in the constellation of Canis Major, and the brightest star in our sky other than the Sun, has a magnitude of -1.5 and the Sun a magnitude of about -26 . Fainter stars, with magnitudes greater than 6 can also be accommodated. Binoculars or telescopes will reach objects far fainter than the eye can discern, which therefore have magnitudes greater than 6.

Wavelength Issues

Stars are not sources of monochromatic light; they emit a broad spectrum extending across the nominal 400–800 nm band of visible wavelengths and beyond in both the longer and shorter wavelength directions. The apparent color of a star depends upon the wavelength at which the peak brightness occurs, which in turn depends upon its photospheric temperature. The consequent star colors range from red to blue (and into the infrared for very cool stars).

The interstellar and atmospheric transmissivities are wavelength dependent, and in general so is the sensitivity of devices typically used to measure light intensity. This variability is particularly marked in the case of the human eye, which may differ between individuals and also with the same individuals, depending upon health, fatigue, etc. A classic example of the need to take this wavelength dependence into account is evident in old photographs of the constellation of Orion, made using orthochromatic photographic emulsions, which have extremely low sensitivity to the red end of the visual spectrum. Betelgeuse (α Orionis), the brightest star in the constellation (a red giant), is not visible, whereas Rigel, a blue-white star, is very conspicuous. A more extreme, although nonastronomical example is in a photograph (again using an orthochromatic emulsion) of the cab of an early steam locomotive, looking into the open firebox, which shows no fire at all, although the boiler pressure gauge shows a vigorous fire must be present. To maintain the utility of the apparent magnitude observations, it is necessary to deal with wavelength dependencies, but this needs to be done in a manner that is

both standardized and does not overly complicate the measurement process.

Stellar Spectral Types

The concept of “stellar spectral type” is, to a large extent, an indicator of a star’s photospheric temperature, i.e., its color. This way to describe stars is therefore intricately mixed with the magnitude/color issue, so a short description is included here. Stars come in a wide range of colors, brightnesses, and masses and with different spectral line signatures, so it was deemed useful to develop some sort of classification framework toward providing a coherent overall picture of star types and stellar evolution. The first attempts were made at a time when stellar astrophysics was not a highly developed subject. One early system to classify stars used alphabetic labels. However, as knowledge improved, the trend was to classify on the basis of photospheric temperature and spectral line signatures. Some classes were found to be redundant, and the sequence of remaining classes had to be rearranged, so they were no longer in alphabetical order. The new system is in order of decreasing temperature and became O, B, A, F, G, K, M, L, T, Y. This arbitrary sequence of letters is remembered using the mnemonic “Oh Be A Fine Girl and Kiss Me. Like This? Yes!” This sequence is further subdivided using numerical interpolation (e.g., G2, A5, M0, etc.). The classes and their corresponding photospheric temperatures and colors are summarized in Table 1. In the case of the Y0 class at 600 K, these cool stars are usually described as “brown,” although the color would be more accurately described as an extremely dull red or perhaps not visible at all at optical wavelengths since its spectral peak lies in the infrared region.

The UBV(RI) Magnitude System

Stellar spectra are generally (almost) blackbody spectra corresponding to the stars’ photospheric temperatures, with superimposed absorption

Apparent **Magnitude,** **Astronomy,**
Table 1 Photospheric temperatures/colors and spectral types

Photospheric temperature (K)	Spectral type	Color
35,000	O0	Blue
30,000	B0	Blue white
10,000	A0	White
7,500	F0	Pale yellow
6,000	G0	Yellow
5,000	K0	Orange
3,500	M0	Red
2,000	L0	Dull red
1,200	T0	Very dull red
600	Y0	“Brown”

lines. Magnitude determination applies to the thermal emission only. Figure 1 shows blackbody spectra for the photospheric temperatures and spectral types listed in Table 1.

The required amplitude and wavelength-related information is included in a star’s spectrum. Stellar spectra are the primary data source for most stellar astrophysics. However, each spectrum contains a lot of information, and when studies involving large numbers of stars, or where measurements that are relatively simple and reproducible are needed, an alternative system would be useful.

To meet these needs, Johnson and Morgan [4] developed the three-filter, UBV system, which is still widely used. This method uses magnitude determinations made using three standard filters, designated U (ultraviolet), B (blue), and V (visible), respectively. To better describe cool, red stars, two additional bands have been added: R (red) and I (infrared). The objective is to describe the thermal spectrum using a small list of standardized parameters. The nominal wavelength ranges (bandwidths) are listed in Table 2.

The shapes of the filter passbands for devices currently in use are far from rectangular, but there has been an effort to at least standardize the filters to improve comparability of data between sources. The I and R bands are not so cleanly

Apparent Magnitude, Astronomy, Fig. 1 Blackbody spectra corresponding to the photospheric temperatures of stars of spectral types O0, B0, A0, F0, G0, K0, M0, L0, T0, and Y0. The nominal bandwidths of the U, B, V, R, and I filters are shown. The spectra are all normalized

Apparent Magnitude, Astronomy, Table 2 Nominal filter bandwidths for stellar magnitude measurements

Band designation	Band name	Low end (nm)	High end (nm)	Bandwidth (nm)
U	Ultraviolet	320	400	80
B	Blue	400	500	100
V	Visible	500	700	200
R	Red	550	800	250
I	Infrared	700	900	200

delineated. The I band overlaps the V band, and the R band overlaps the I band. Some institutions have added additional filter bands to suit their particular research needs.

Table 1 also shows the wavelength ranges passed by the U, V, B, R, and I filters. These rectangular passbands are not representative of the passbands of existing filters. The bandwidths are also shown using arrows, so the overlapping bands are more clearly discernible.

For most purposes, the U, B, and V magnitudes are sufficient, and it is possible to describe the photospheric thermal spectrum of most stars using V and the magnitude differences U–B and B–V. Since the magnitudes are logarithmic

quantities, the differences actually describe brightness ratios, i.e.,

$$(U - B) = -2.5 \log_{10} \left(\frac{\frac{P_U}{\Delta\lambda_U}}{\frac{P_B}{\Delta\lambda_B}} \right) \quad (9)$$

and

$$(B - V) = -2.5 \log_{10} \left(\frac{\frac{P_B}{\Delta\lambda_B}}{\frac{P_V}{\Delta\lambda_V}} \right) \quad (10)$$

where P is the total power passing through the filter. Conventionally, the values are offset so that a star of spectral type A0 is characterized by U–B

Apparent Magnitude, Astronomy, Fig. 2 U-B and B-V plotted against the logarithm of the photospheric temperature for the blackbody spectra in Fig. 1. The spectral

types of the stars modeled are shown. In each case the types are M0, K0, etc.

and $B-V = 0$. If the filter passbands are assumed to be rectangular, the spectra in Fig. 1 produce the U-B and B-V values shown in Fig. 2. It can be seen that these values provide a good estimator for the star's photospheric temperature. The letters above the data points on the graph are the spectral types of stars with those particular photospheric temperatures. Since stellar spectral types are temperature dependent, the UVB photometric system provides an estimator for spectral type.

However, in reality, filter passbands are not rectangular, and stellar flux densities may vary dramatically with wavelength, so simply averaging over assumed rectangular passbands will not produce useful results. Unfortunately, making filters with rectangular passbands is very difficult, and the more effort dedicated to achieving this also makes the filters harder to reproduce, which is a critical issue where standardization between instruments and observatories is important.

For this reason, a set of standardized filters are used. These are generally those used by Johnson and Morgan [4]. They do not have rectangular passbands but have the great advantage of being

fairly easy to reproduce. The wide adoption of these standard filters for stellar photometry makes it possible to combine data from different sources.

B-V and Stellar Spectral Types

Figure 3 shows a plot of spectral type against B-V for the stars listed in the bright star section of the *Observer's Handbook* of the Royal Astronomical Society of Canada (RASC) [5]. For convenience in plotting, the spectral types O0, B0, A0, F0, G0, K0, and M0 are represented by the numbers, 1, 2, 3, 4, 5, 6, and 7 respectively. The subdivisions within each spectral class are coded as a decimal; for example, stars of spectral classes O5, A0, F6, G2, K5, and M3 would respectively be represented as 1.2, 3.0, 4.6, 5.2, 6.5, and 7.3. The point surrounded by the yellow halo is the Sun. The empirical equation can be used to estimate the spectral type from B-V.

Today, the term "apparent magnitude" is generally taken to be equivalent to "visual

Apparent Magnitude, Astronomy, Fig. 3 Numerical representation of spectral types plotted against B–V values for the stars in the RASC list of brightest stars

magnitude”: a magnitude measurement made using a V filter.

Absorption and Scattering

To reach terrestrial observers, the starlight has to travel through the interstellar medium and then through the Earth’s atmosphere. Both of these media contain dust, molecules, and atoms that absorb or scatter some of the starlight, with the extent of these processes usually being wavelength dependent. The result is generally a weakening and reddening of the light. There are three main processes:

- Scattering at wavelengths coinciding with molecular or atomic resonances, where the directional light drives electrons to higher energy states and then is reradiated isotropically.
- Rayleigh scattering, which is scattering by particles smaller than the wavelength of the light (mainly atoms and molecules). This is strongest at shorter wavelengths and is what causes

the sky to look blue and sunsets to be rich in reds and golds.

- Scattering off larger particles: This shows much less of a variation with wavelength. In the atmosphere, the main scattering agents are aerosols, composed of small droplets of water or pollutants. This mode of scattering is less likely in interstellar space but may occur where there are clouds of larger particles. Fog and mist are good examples.

If an intrinsically stellar measurement is needed, then both the interstellar and atmospheric effects on the starlight have to be determined and removed. Although even the densest interstellar clouds are more rarefied than the best achievable laboratory vacuum, the very large distances the light has to traverse means it has to pass through an enormous amount of material. However, in this entry the emphasis is on making measurements that are comparable between observers and observing sites, so the measurements need only be referred to the top of the Earth’s atmosphere, so interstellar effects are common to all observers and not further discussed here.

The attenuation imposed by the atmosphere is by processes similar to those attenuating and scattering the light in the interstellar medium. However, an important difference is that in the case of the interstellar medium, the light path from star to the Earth is common to all observers and changes very slowly with time, whereas in the case of the atmosphere, the rotation of the Earth changes the light path through the atmosphere quickly enough to offer a means to estimate the stellar magnitude that would be observed in the absence of atmospheric attenuation. It is assumed that the transmissivity of the atmosphere is related to the total mass of atmosphere that the light passes through. If we look in the direction of the zenith (zenith angle = 0), we are looking through a certain total mass of air:

$$M_0 = \int_0^\infty \rho(h)dh \quad (11)$$

where $\rho(h)$ is the atmospheric density as a function of height. The “0” suffix indicates a quantity measured when looking at the zenith. The *transmissivity* of the atmosphere (the fraction of light arriving at the top of the atmosphere that reaches the ground) from an object at the zenith is defined as

$$F_0(\lambda) = F_{00}(\lambda) \exp(-\eta(\lambda)M_0) \quad (12)$$

where η is an absorption parameter and M_0 the mass of air through which the light is passing. The flux density from the star is a function of wavelength and so is the atmospheric attenuation.

Assuming the magnitude measurements are restricted to zenith angles smaller than about 65° (elevation angles larger than 25°), the atmosphere can be treated as a stratified slab. In this case, the air mass through which the light passes is a simple function of zenith angle:

$$M_z = M_0 \sec(z) \quad (13)$$

It is unlikely that there will be any need to separate M_0 and η , so they can be combined into a single parameter $\beta(\lambda)$, and so for a zenith angle z

$$F_z(\lambda) = F_{00}(\lambda) \exp(-\beta(\lambda) \sec(z)) \quad (14)$$

We have two ways to define the effect of the atmosphere on the light. The *transmissivity* (α) is the fraction of the incident light reaching the ground:

$$\alpha = \frac{F_z(\lambda)}{F_{00}(\lambda)} \quad (15)$$

An alternative is define an *opacity* (ξ), where

$$\xi(\lambda) = \beta(\lambda) \sec(z) \quad (16)$$

So

$$\begin{aligned} \alpha &= \exp(-\xi) \\ \text{or} \\ \xi &= -\log(\alpha) \end{aligned} \quad (17)$$

As the atmosphere ranges from completely transparent to completely opaque, the transmissivity (α) ranges from one to zero and the opacity (ξ) goes from zero to infinity.

The slab atmosphere model offers a means to estimate the magnitude of the star in the absence of the atmosphere, using a method attributed to Pierre Bouguer and discussed by Dufay [6]. Using Eqs. 7 and 12,

$$m_z(\lambda) - m_{00}(\lambda) = -2.5 \log_{10} \left(\frac{F_{00} \exp(-\beta(\lambda) \sec(z))}{F_{00}} \right) \quad (18)$$

So

$$\begin{aligned} m_z(\lambda) &= m_{00}(\lambda) \\ &+ 2.5 \log_{10}(e) \beta(\lambda) \sec(z) \end{aligned} \quad (19)$$

where m_z is the measured stellar magnitude at a zenith angle z and m_{00} is the magnitude of the star before it is attenuated by the atmosphere. Equation 16 shows a simple, linear relationship between m_z and $\sec(z)$. Therefore, if a series of magnitude measurements for a star are made over a range of zenith angles, a plot of m_z against $\sec(z)$

will have a slope $2.5 \log_{10}(e) \beta(\lambda)$ and intercept $m_{\infty}(\lambda)$, the magnitude of the star as it would be measured at the top of the Earth's atmosphere. This process is repeated for the U, B, and V filter bands, to obtain the U, B, and V magnitudes corrected for atmospheric absorption.

Summary

“Apparent magnitude” is literally a measure of how bright something looks. As such it includes the effects of observing conditions, locale, and the nature of the observer. In addition, stars come in a range of colors, depending on their temperatures. To make this measure useful to all terrestrial observers, it has to be less apparent and more objective. This is achieved by making stellar magnitude measurements using three filters, each covering a standard wavelength range, designated U, B, and V. The latter, the visual magnitude, covering the bandwidth 500–700 nm, replaces apparent magnitude.

Definition

Visual appearance refers to how things look to observers. Objects have physical properties, and in this regard, optical properties are usually most relevant together with size, texture, shape, etc. But what finally matters for vision is the appearance that objects have for an observer (human observers will be mainly referred to in this article; however, this is not restrictive to human beings since there are many other living species that have similar visual processing systems). The American Society for Testing and Materials (ASTM) as well as the International Commission on Illumination (CIE) define appearance as the aspect of visual experience by which objects are recognized [1, 2]. The ASTM specifies, furthermore, the definition of appearance from a psychophysical point of view: “perception in which the spectral and geometric aspects of a visual stimulus are integrated with its illuminating and viewing environment.” The physical properties have, of course, influence on the way things look, but also the

neurophysiology and psychology of vision play a very important role in determining how objects and the world appear to humans. Thus, it is important to understand visual appearance not merely in regard to physical aspects but as a sensation produced by the visual system when processing stimuli channeled by means of light – visible radiation. Visual appearance, understood as a visual sensation, i.e., what humans see, has certain attributes, which are also visual sensations. These include color, visual texture, gloss, and transparency. In the ASTM definition the “spectral aspects” refer, of course, to color, and the remaining aspects (including the perceived shape, size, etc. of objects) are usually considered as “geometric aspects.” From these visual sensations observers get information about the environment and build their knowledge of the external world, which allows them to interact with the environment and with other individuals.

Historical Review of Studies on Visual Appearance

Under the heading of visual appearance a number of aspects are included such as color, texture, gloss, transparency, and also the shape and size of perceived objects or stimuli. The psychologist ► [David Katz](#) was probably the first to understand the various kinds of phenomena that always accompany the perception of color [3]. He describes different modes of color appearance: surface color, film color, volume color, specular colors, transparent colors, perception of luster, etc. By the middle of the twentieth century, Arthur Pope realized that, in order to define a color with accuracy, i.e., giving account for different modes in which a color may appear, more than the three usual variables (hue, lightness, and saturation) are needed [4, p. 28].

In 1953, the Committee on Colorimetry of the Optical Society of America published a book in which visual perception is classified into 11 “attributes of modes of appearance” [5]:

1. Brightness (or lightness)
2. Hue

3. Saturation
4. Size
5. Shape
6. Location
7. Flicker
8. Sparkle
9. Transparency
10. Glossiness
11. Luster

Lightness, hue, and saturation (attributes 1, 2, and 3) are the usual variables by which color sensations are described. Size, shape, and location (attributes 4, 5, and 6) are spatial categories of visual perception, which can be included in the category of spatial form. Flicker and sparkle (attributes 7 and 8) involve temporal variations in the perception of light. Finally, transparency, glossiness, and luster (attributes 9, 10, and 11) refer to the perception of different spatial distributions of light, aspects that will be included in the category of “cesia” to be described in the next section.

Richard Hunter proposed a classification of the geometric attributes of visual appearance [6]. He defined six different types of gloss and developed instruments for the measurement of some of these phenomena: ► [goniophotometers](#), diffuse-reflection and specular-reflection meters, ► [glossmeters](#), diffuse- and specular-transmission meters, etc. Before Hunter, August H. Pfund had already described an instrument for measuring gloss [7]. The American Society for Testing and Materials has standardized the measurement of various physical aspects related to visual appearance [8–11] and published a glossary of standard terminology [1].

Robert Hunt has developed a hypothesis for the measurement of color appearance under different conditions of illumination and observation, taking color as the central point of his study [12]. Sven Hesselgren observed that visual sensations, such as luster, reflection, and gloss, are not perceived as belonging to the color of an object but as something separate from color [13]. Ralph Evans, like Pope, also realized that the three variables normally used to define color are not enough to characterize color under different modes of

appearance [14]. Evans concluded that it would be necessary to define at least five variables. In these conceptions, the phenomena of appearance have always been considered as aspects that accompany color sensations.

Other researchers have studied, either partially or globally, the aspects of visual appearance related to the different modes of distribution of light in space. Fabio Metelli tackled the problem of *transparency* from a phenomenological point of view, establishing a clear difference between physical and perceived transparency and developing a model that predicts the conditions under which the perception of achromatic transparency is possible [15]. Osvaldo Da Pos, following Metelli, enlarged the model to study the perception of chromatic transparency [16].

John Hutchings studied the phenomenon of translucency and its importance for the visual qualities of food. In articles published in 1993 and 1995 he integrated all the aspects into a model of total appearance [17, 18]. However, this model is mainly oriented toward the analysis of food [19] and for this reason includes also nonvisual aspects of appearance such as smell, taste (flavor), and also texture as felt in the mouth, in addition to visual texture. Paul Green-Armytage proposed a three-dimensional model to organize what he called “qualities of surfaces” [20, 21]. Subsequently he introduced the term “*tincture*,” borrowed from heraldry, to encompass color, texture, and *cesia* [22]. Robert Sève tackled the specific problem of gloss [23]. Michael Brill used the model of Metelli to formulate a series of rules for the perception of chromatic translucency [24].

In 2006, a technical committee of the CIE (Commission Internationale de l’Eclairage, International Commission on Illumination) published a report to set a framework for the measurement of visual appearance [2].

A Classification of Visual Appearance into Four Categories

It is possible to analyze a given scene and try to understand how most humans separate and

categorize (by means of concepts and words) the main visual aspects involved. If the features shown in Fig. 1a are selected, people would agree on saying that they are different colors. If other features are selected, such as those shown in Fig. 1b, people will call them shapes (spatial forms). If the features selected in Fig. 1c are shown, people would call them textures. Finally, for the features selected in Fig. 1d the term *cesia* has been proposed.

Color can be defined as the aspect of visual appearance that results from the perception of different spectral compositions of light; it is what people are referring to when they say that some object or light stimulus is red, green, yellow, blue, black, white, gray, etc.

Spatial forms, or shapes, are built in consciousness from the perception of borders and their integration, so that they enclose or delimitate a portion of space. Spatial forms can be one dimensional (a straight line, a curved line, an irregular line, etc., which separate one portion of space from another), two dimensional (a triangle, square, circle, irregular surfaces, etc.), or three dimensional (a cube, a prism, a pyramid, a tetrahedron, a sphere, irregular volumes, etc.). They can have different shapes (as usually defined by the previous names), but they can also differ in size (length, surface, and volume) and proportion (defined by the relationships among the dimensions of the shape: length, width, and height).

Visual textures arise from the perception of sets of small elements that appear repeated in a surface or volume. The category of texture applies when these elements have no individual significance and are interpreted as making a whole, building a pattern that can be more or less regular or irregular. Visual textures can be distinguished and described by different variables or dimensions. These variables include density (the elements of the texture can be sparse, dense, or intermediate), predominant directionality (the elements can vary in direction or have no predominant directionality), and, of course, the shape and size of the relatively small elements whose repetition composes the texture. Visually perceived textures may be two dimensional (without relief) or three

Appearance, Fig. 1 The same scene with different visual features selected and categorized: (a) Different *colors*. (b) Different *spatial forms* or shapes that appear defined by their borders. (c) If attention is paid to certain regularities or repetition of elements on the objects, the notion of

texture can be applied. (d) Other visual characteristics such as the transparency of the glass, the white matte opacity of the paper towel, the metallic luster of the sugar pot, the glossy and semitransparent aspect of the ice cubes, and other similar ones have been given the term *cesia*

dimensional (with relief), the latter being also perceived by touch [25].

Beyond color, spatial forms, and textures, there are some other visual appearances that depend on the way in which differences in the spatial distribution of light are perceived. It is these spatial distributions of light that cause things to be seen as transparent or opaque, glossy or matte, or with intermediate appearances between these. Since there has not been a single global name or category to refer to these aspects, the neologism *cesia* has been coined for them.

Cesia

“Cesia” is a term invented around 1980 by César Jannello, to designate the perceptions resulting from the different spatial distributions of light. This concept was developed mainly by Caivano [26–29]. Cesia encompasses all the visual

sensations from transparency to translucency, matte opacity to mirror-like appearance (passing through glossy appearance), and lightness to darkness. Cesia are related to color in the sense that both are different aspects of the perception of light, and color deals also with lightness and darkness. But there are aspects that cannot be described by the three classical color dimensions of hue, lightness, and saturation. In this sense, cesia constitutes a category that can be added to the categories of color, visual texture, and spatial form in order to extend the possibilities of describing and classifying visual appearance. Three dimensions or variables can define cesia with respect to the perception of how light interacts with objects: permeability (from opaque to transparent), diffusivity (from regular to diffuse), and darkness (from light to dark). Light can be reflected or transmitted by objects, either diffusely or regularly, and it is the perception of these phenomena that is covered by the term “cesia.” For

Appearance,
Fig. 2 Cesia: processes followed by light falling on objects, and the way these stimuli are usually perceived

instance, a surface that reflects light in a diffuse way will normally be perceived to be matte. If a surface reflects light with a certain specular component it will be perceived as glossy or mirror like. If it transmits light diffusely it will be seen as translucent, and if it transmits light in a regular way it will be seen as transparent. Finally, a surface that absorbs most of the light will appear dark or black (Fig. 2).

A three-dimensional model has been proposed to organize the three variables of cesia (permeability, diffusivity, and darkness). The model is a kind of inverted pyramid, with four vertices on the top for the sensations of matte appearance, mirror-like appearance, translucency, and transparency. The connections among these form scales with a variation of permeability (or the opposite, opacity) in one direction and scales with a variation of diffusivity (or the opposite, regularity) in a perpendicular direction. From any of these points, scales going down in lightness (or increasing darkness) connect to the point that is the place for black (Fig. 3).

In both color and cesia the relationship between stimulus and sensation is not fixed but

depends on three main factors – illumination, object, and observer – and is affected by other factors such as visual context, adaptation, contrast, etc. Some of these factors have been studied and exemplified with photographs by Maria P. Giglio [30]. To mention just an example: depending on the distance taken by the observer, an element can be perceived as more opaque or transparent, even when the physical arrangements of objects do not change (Fig. 4).

Color and cesia are closely connected because of their relationship with light; both are different aspects of the perception of light that contribute to the visual appearance of objects. The dimension of lightness/darkness is shared by color and cesia, being the link that connects both phenomena. Color and cesia interact thereby expanding the countless number of different visual appearances that humans are able to perceive. When Ludwig Wittgenstein, in his *Remarks on Color* [31], is concerned with the different types of white, yellow and golden, gray and silver, “black” mirrors, etc. and when he says, “Opaqueness is not a property of the white color; any more than

Appearance, Fig. 3 The three-dimensional model of cesias

Appearance, Fig. 4 A screened shutter that covers a shop window goes from near opacity to near transparency. When the observer is at a certain distance, the surface of the shutter looks more opaque than transparent and objects

behind it cannot be seen. When the observer gets closer, the small holes of the shutter tend to disappear, and the effect of transparency increases. (Photograph: M. Giglio)

transparency is a property of the green,” he is dealing, in reality, with this aspect that we call cesia.

Models to Organize Different Aspects of Visual Appearance

Roberto Daniel Lozano, one of the members of the CIE technical committee 1-65, proposed a new approach to appearance characterization, with a model that classifies visual appearance

according to three main categories (color, cesia, and spatiality), which in turn includes subcategories and shows the interrelations and intermediate aspects among them (Fig. 5) [32].

More recently, Paul Green-Armytage proposed a model to link different modes and different aspects of appearance [33, 34]. The model shows relationships between the surface, volume, and illuminant modes of appearance as well as transparency, translucency, opacity, texture, gloss, metallic luster, and luminosity. Caivano identifies the five vertices of his inverted pyramid

Appearance, Fig. 5 The classification of visual appearance proposed by Lozano. (Reproduced with permission of R. D. Lozano)

model of cesia (Fig. 3) as “primary sensations” [27]. These are opaque white, translucent white, transparent clear, mirror like, and black. Caivano’s three-dimensional inverted pyramid can be presented in two dimensions (Fig. 6).

This two-dimensional representation of Caivano’s model is at the center of Green-Armytage’s model. Green-Armytage makes a distinction between gloss and metallic luster (mirror like), noting that scales can be constructed from a matte surface to surfaces that are increasingly glossy in one direction and from a matte surface to surfaces with increasing metallic luster in

another direction. He also notes that scales can be constructed with increasing texture from three different starting points: smooth matte, smooth gloss, and smooth metallic luster. Matte, glossy, textured, and metallic aspects of appearance are all characteristics of the surface mode of appearance. The volume mode can vary between clear (transparent) and cloudy (translucent). In the illuminant mode light sources can appear in varying degrees of brightness with a notional maximum that can be described as glare. To Caivano’s five primary sensations Green-Armytage adds three more: gloss white, textured white, and white

Appearance, Fig. 6 Two-dimensional representation of Caivano’s inverted pyramid model of cesia

Appearance, Fig. 7 Hue sequences in different aspects of appearance linked to Green-Armytage’s model

light glare. Each of the seven other primary sensations can be connected with scales to black, and these scales can, in turn, serve as the achromatic axes of order systems for colors that are opaque, translucent, transparent, and metallic (mirror like), as well as glossy, textured, and self-luminous. Green-Armytage’s model, with color circles to correspond with the different primary sensations, is shown in Fig. 7.

Increasing apparent intensities of illumination can be represented on lines which converge at

white light glare. The coherence of a light source, which affects appearances, can also be represented on the diagram. “Hard” light, as from direct sunlight and under which objects cast clearly defined shadows, is represented on the line connecting transparent clear to white light glare, and “soft” light, as from a heavily overcast sky and under which no shadows are cast, is represented on the line connecting translucent white to white light glare.

The various models described here can go some way to increasing awareness of the different aspects of appearance, and how they can be related, but no model can encompass the full experience of seeing the world in space and time.

Environmental Design and Engineering,
London, UK

Synonyms

[Lighting design](#)

Definition

Architectural lighting design is the design and implementation of daylight and electric lighting provision in urban and architectural environments. This process requires conceptual thinking, design development, and illuminating engineering to produce lit environments for people's work and leisure.

Lighting Quality

The built environment in which people live and work is composed of a variety of building types. In a shopping mall, retail units are expected to be

colorful and attractive. In an art gallery, it is necessary to be able to appreciate the color and detail in a painting, and when walking in the city, people expect to remain safe and secure. All these impressions can be dramatically affected by the lighting. Boyce has suggested that *bad* lighting “does not allow you to see what you need to see, quickly and easily and/or causes you discomfort” [1]. If the lighting designer overcomes these problems, then they can produce – at best – *indifferent* lighting. Only when the configuration of the windows and surfaces or the characteristics of the lighting installation “lift the spirits”, can the environment be described as *good* lighting.

The task of the lighting designer or a lighting engineer is to determine the character of a lit space, whether it be a street, a townscape, or a room, and then to arrange the sources of light, be they daylight or electric light, to achieve this desired character.

Objectives of Design

The purpose of lighting is to provide for the needs of people who are going to use the built environment that is being created, and any person designing the lighting will wish to create a quality lit environment. However, this raises the question about what constitutes good quality lighting? To answer that question, the needs of the people who are going to use the building that is to be lit require consideration. In general terms, the users of a building are going to want lighting so that they can see things easily, they will require the lighting to set the correct ambience, and if they are going to remain in the building for long periods, they may well benefit from the biological impact that the lighting may have on their endocrine systems. These topics are covered in more detail in the following sections.

Light for Seeing

Before considering what sort of lighting is required, it is first essential to consider what the occupants of a building need to see and what the consequences are of them not being able to see. Consider two cases: a surgeon undertaking heart

surgery and an office junior doing a filing task. Both of them need to be able to see small objects – in the case of the surgeon, this may be small blood vessels; whereas, for the office junior, he has to read the small text on the documents he is working with. However, the office junior is normally dealing with high contrast printed text, while the surgeon has the problem of distinguishing objects that are very similar in color and reflectance. Moreover, if the surgeon makes a mistake, it could kill a patient, but an error in filing can be easily rectified. Thus, it is normal to have more than ten times as much light available in an operating theatre compared to an office.

Selecting an appropriate level of lighting for a given visual task is bound to be complex as a number of factors need to be considered. These include the complexity of the visual task, the visual acuity of the person performing the task, the length of time for which the task is performed, and the consequences of any mistakes. These factors need to be set against the cost of providing the lighting and the other negative consequences of providing lighting such as energy use and associated greenhouse gas emissions.

To help lighting designers in the selection of appropriate lighting conditions, there are a number of codes and standards available which provide recommendations for the lighting conditions considered necessary for a whole range of different tasks. These documents have evolved over a number of years and in general provide a consensus view of the lighting needs in a typical installation. However, the lighting requirements for every installation are potentially different and so the guidance provided by codes and standards should usually be regarded as a starting point from which the design may be developed; however, there are occasionally situations where the national regulations insist that particular illuminance values are used in given circumstances. Good examples of such codes are the *IES Handbook* [2], the *SLL Code for Lighting* [3], and *ISO 8995-1:2002* [4].

While considering the required illuminance necessary for a particular task, it is also important to consider other factors such as freedom from glare and the necessary color properties of the

light sources used. Most codes and standards also give advice on these issues.

Setting the Ambience

Every lighting installation sends a message to the users of the building; it is the art of good lighting design to ensure that this message complements the message sent by the architecture and that the overall message is appropriate to the use of the building. Consider the lighting in a supermarket and compare it with the lighting in an up-market boutique. In many ways, the lighting has a similar job to do – it must show off the goods in the store so that people choose to buy them. However, the style of the lighting is radically different as supermarket style lighting in the boutique would send entirely the wrong message to potential customers.

There is no simple way of providing lighting that perfectly provides the correct message for a given environment. There have been many studies into how to characterize the lit environment of places that are considered to be well lit, and in general, the results have been patchy and limited in validity to the environment in which they were assessed. Section “[A Framework for Design](#)” gives some basic advice, but it is always going to involve a series of complex subjective judgments to get the lighting right and the reliance on simple codes will not suffice.

Biological Impact

The nonvisual or biological effects of light have their biggest impact on the regulation of the human sleep/wake cycle. Exposure to high levels of light may be used to shift the time of peoples’ body clocks and may also be used to boost the alertness of people. These biological effects happen naturally to people in an outdoor environment; however, in many interiors, there is not sufficient light to provide the necessary stimulus to the human endocrine system.

The most logical way to resolve the problem is to provide interiors with good levels of daylight. Light sources may be used, biased toward the blue and blue/green regions of the visible spectrum (within acceptable safety limits), if the objective of the design is to promote the nonimage-forming impacts of light [5].

A Framework for Design

The objective for anyone trying to design lighting is to provide good quality lighting. The construction of a new building or the refurbishment of an existing one comprises a series of construction stages from design through construction to the final use of the building or area. Lighting should be designed by someone who has the ability to make the necessary aesthetic judgments about how the lighting will impact on the space being lit while at the same time engineering the lighting equipment into a functioning system. Therefore, the lighting designer or lighting engineer can make a particular contribution or intervention within the *design* phase. Here, a lighting design concept is proposed where outline proposals for the arrangement of structural and building services are made. The design is then developed in detail to decide on the relationship between the electric lighting systems and the daylighting, and finally a technical specification is drawn up to coordinate the various components and architectural elements.

At each of these stages, the designer will be considering a variety of factors. Veitch has suggested that designers should consider the well-being of the individual user, the integration with the architecture, and the economics of the lighting installation [6]. Loe has proposed a useful variation in a framework for design [7], which comprises the following elements (Fig. 1).

Lighting for visual function: The lighting should enable users to undertake visual tasks without visual discomfort. Recommendations are made concerning the level of light on the task (illuminance) and the uniformity of light on the task. It is also important to prevent unwanted brightness in the visual field (the control of glare).

Lighting for visual amenity: People prefer an architectural room or urban space to contain a degree of *visual lightness* (a sense of lightness and airiness) and *visual interest* (a variation in light and shade). The color appearance of the space should be appropriate for the application, e.g., warm and inviting or cool and professional. The objects and people in the space need to be lit pleasingly.

Architectural Lighting,
Fig. 1 A framework for lighting design (after Loe). The relative weight given to each element of the framework depends upon the requirements of the lighting design

Energy efficiency and sustainability in lighting: The lighting installation must contribute to sustainability by maximizing the use of daylighting and ensuring that energy efficient light sources and light fittings are specified. Reducing energy consumption is a matter of reducing the power load of the lighting components and the hours of use. This can be achieved by the effective use of lighting control systems (switching, dimming, and linking to daylight levels).

Lighting installation maintenance: The lighting designer or engineer must specify a lighting installation that can be easily maintained by the client or user. It should be easy to clean and relamp the fittings to ensure that the installation continues to deliver the appropriate lighting. Poor maintenance of an installation will lead to some of the lighting points failing and this sends the message that no one cares about the space.

Lighting costs: The cost of the installation needs to be controlled and a distinction is made between *capital* costs (for the original lighting equipment) and *running* costs (the cost of operating the lighting system as designed).

Architectural integration: An understanding of the intent of the architect and the character of the space in terms of dimensions, finishes, textures, and materials is essential. Only then can electric lighting systems be properly integrated into the fabric of the building to produce the appropriate lighting effect.

These factors are described in greater detail in the *SLL Lighting Handbook* [8]. It should be noted that they are occasionally legal requirements for lighting in certain areas.

Daylighting

It is useful to think of the elements of the city and the town and the constituent buildings as being under the vast dome of the sky. In many climates, there will be days in which this dome is covered by a thick layer of cloud – the fully overcast sky, which might be termed the *diffuse* component. As the conditions change, the clouds begin to thin and the sun emerges. This source has a very different character – a sharp beam and the ability to

create shadows – this may be called the *direct* component. These two components of daylighting are varying continually throughout the day and throughout the year.

The lighting designer works at different scales of analysis. For example, the designer might seek to optimize the spacing between apartment blocks to ensure that certain apartments are not restricted in the amount of light that they receive. The designer might also seek to ensure that courtyards or plazas receive enough sunlight or are shaded in certain climates. Simulation software has the capability to demonstrate the effect of sun position on buildings. Stereographic sun paths are available to show the passage of the sun in the sky (Fig. 2).

The lighting designer can also work in conjunction with the architect to ensure that the individual rooms and spaces within a building receive sufficient daylighting. The traditional way to pierce the solid wall of a building is by a vertical window. The clerestory window and the rooflight provide ways of allowing daylight to enter the building to provide a different character to the space. This is because they are facing different parts of the sky. The atrium is a useful device, historically and in contemporary buildings, to let natural light deep into the building. It is also possible to “borrow” light from one space to another using transparent partitions.

Contemporary buildings have a framed steel or concrete structure in which the structure defines the architecture. The introduction of daylight into the building thus becomes a result of the structural decisions that have been made. This is the province of facade engineering whereby the transparent partitions that clothe the structure are then subject to varying architectural treatment in terms of the choice and specification of the glazing (solar control or electrochromic materials) and whether shading is to be added (louvres and *brise-soleil*). It is at this point that daylight availability is estimated by calculation of the daylight factor or methods of calculation of cumulative daylight exposure. The European standard for daylight in buildings [9] provides guidance on the necessary qualities of daylight to necessary to provide a successfully daylit space.

Architectural Lighting,

Fig. 2 A plot of the sun's position in the sky for London (51°N Latitude) denoted by its azimuth angle in plan and altitude above the horizon

When designing the daylight in a building, it is also important to consider the quality of the view out (and in) that the windows may give.

Electric Lighting

There are a plethora of new technologies for lighting, e.g., light-emitting diodes (LEDs), and a variety of lamp technologies including high-pressure discharge lamps, fluorescent lamps, and incandescent lamps. The designer has the ability to control both the intensity and the color of the light that is emitted from these sources.

Consider the public square in the town or city. An appropriate choice of lamp on an amenity lighting column can attractively reveal the features on the faces of fellow street users to ensure safety and security, and the appropriate color choice can dynamically reveal the city.

The architectural façade can take a variety of forms: neoclassical, turn of the century, international modern, or contemporary. It is the task of the lighting designer to reveal the characteristics of the architecture without distortion, to complement and enhance the architectural detail. It is important to ensure also that each architectural element is read as a whole – from the base to the roof. Again the judicious choice of color and intensity of the light source in conjunction with an appropriate lighting fitting can ensure that the architectural intention is maintained.

Moving indoors the choice of light source remains critical in terms of its color, its life, and its efficiency. Such sources are housed within light fittings (*luminaires*) – used individually or more typically in arrays to provide layers of lighting or inbuilt into the architecture.

An individual luminaire can be used to accent individual features, and arrays of luminaires

Architectural Lighting, Fig. 3 The Pantheon in Rome

(linear and modular in form) can be arranged within the various architectural spaces to provide lighting for tasks and to reveal the architecture of the space with its characteristic finishes and materials. Care is taken by the designer to ensure that the user of the space is not subject to unwanted glare from the fittings and that the overall brightness of a sequence of spaces from one to the next is kept within reasonable bounds (*adaptation*).

The design of an individual luminaire is a complex process in itself. It must be designed to house a particular light source which might be spherical, linear, or elliptical. The flux from the source must be possibly redirected into the required direction by the use of a reflector and then the beam from the lamp must be further refined by optical elements such as diffusers, lenses, or louvres. The fitting must be electrically safe, must not overheat, and be mechanically strong – these are common requirements even though the physical form of the luminaire might be quite different cf. a downlighter in a conference center to a street lighting bollard. The designer must also consider the appearance of the fitting when it is lit and when it is unlit and ensure that

**Architectural Lighting,
Fig. 4** The City of Lyon at
night

Architectural Lighting,
Fig. 5 A luminous media
 façade

A

the fittings integrate well with the architectural character of the space.

Endpiece

Architectural lighting has great power. Think of the dramatic daylighting of the Pantheon in Rome (Fig. 3) or the harmonious integration of the lighting of the city of Lyon at night (Fig. 4) or the dynamic lighting of a modern luminous media façade (Fig. 5). But with that power comes responsibility – responsibility that can be accepted by the designer in designing lighting that promotes human comfort and satisfaction.

[Color harmonies for fashion design](#); [Modern art and fashion design](#); [Painted dress](#); [Tactile painting and haute couture](#)

Definition

Art and fashion color design concerns the harmonies of color associations of textile and other materials used for a couturier's aesthetic project. It is an illustration of collaboration of artists and couturiers on the harmonies of color associations in order to create a personal style. They were more closely tied at the turn of the twentieth century than they are today. Artists did not see the difference between creating an original work of art, such as a painting, and designing a textile pattern that would be reproduced many times over. Each was a valid creative act in their eyes. There are a lot of vivid illustrations of the centuries-long love affair between fashion and art of color. Couturiers are past masters at capturing the contemporary *zeitgeist* in their designs, while artists have frequently used clothing as a way to give all-round expression to their aesthetic ideas.

The Role of Art and Fashion

Beginning from the nineteenth century, major changes emerged both in the role of fashion and in the place of art in society. Growing affluence and new social structures gradually turned art, color, and fashion into ways of expressing personal taste and identity. This section presents a historic panorama of the color in the fashion design during the twentieth century, highlighting certain symbolic movements such as the Art Nouveau, the Russian avant-garde, the modernism, pop art, or the kinetic art. It lists the color's harmonies for modern fashion design and describes the tools, ranges, palettes, and techniques which allow personalizing a dress with fantasy and subtlety.

Art has often been a major source of inspiration for dress designers of the twentieth century. Some creations by Liberty, Sonia Delaunay, Liza Schiaparelli, Coco Chanel, Yves Saint Laurent, Givenchy, and Jean-Paul Gauthier can be mentioned. In their practice, the art of color is conveyed to fashion. The designers paraphrase the masters of painting. This connection between art

and fashion is particularly obvious starting in the late nineteenth century.

Fashion and Identity of the Color Palette

Belle Epoque

The artistic principles of the Art Nouveau combine the personal style of expression where the sinuosity of the shape is harmonized well with the mosaic of contrasted colors. The synthesis of practical considerations and of aesthetic natural forms and lines is characterized by color palettes of a great richness. The modern time influenced a lot the development of the fashion design and produced profusion of the ► [polychromy](#) in it. The large selection of paintings by Giovanni Boldini, Auguste Toulmouche, James Tissot, Jean Beraud, and Alfred Stevens – visual artists who reflected the best on the fashion style of the Belle Epoque – is an example of what could be called fashion inspiration in fine arts. Artworks were created in a realistic manner and have not even a touch of stylization typical of modernist art. Figures depicted in these paintings are precise and realistic. However, it would be fair to say that style itself is the subject matter instead of a particular model. Fashion is the main theme and inspiration for these paintings.

Beautiful symbolic women's dresses by famous Austrian artist Gustav Klimt followed, in which he introduced his frescoes and paintings of portrait. Klimt himself drew the blue caftan, a long tunic of oriental style, and many other dresses for Flöge Emilie, his companion for many years, who owned a fashion house in Vienna.

After a visit of a workshop in Vienna, the avant-garde fashion designer Paul Poiret brought the idea of mixing art and fashion to Paris. He opened a Martine school in 1911, a place that was also attractive for artists. He then employed Parisian artists such as Lepape, Ibibe, and Erte on fashion illustrations. He employed the artist Raoul Duffy to design fabric prints and to invent tissues. He went to art galleries and showed his artistic sensibilities by preferring Impressionist paintings at a time when they were new and

unappreciated by the public. Poiret became very interested in modern art and said, “I have always liked painters. It seems to me that we are in the same trade and that they are my colleagues.” The couturier considered himself as an artist first.

Russian Constructivism and Suprematism

The artists of Russian avant-garde in 1915–1935 initiated probably the most intensive and creative art and architectural movement of the twentieth century and became a significant source of any art movement since then. The constructivists defined the chromatic surfaces as fundamental colored elements where the straight lines, the rectangular forms, and the principal colors (yellow, red, blue, black, and white) are used to make a unified composition. The color interdependence simultaneously with the community of ideas formed by the uniformity of geometric contours and the absence of force of gravity, the balance of the unit, and the dynamism of the parts, all form a kind of representation of an ideal cosmos.

Varvara Stepanova, Alexandre Rodchenko, Liubov Popova, and others show their creativity thorough re-energizing new forms and meaning in art and dress design. The key fragments of Russian revolutionary creativity still glow like radium, living on futuristic art and design into the imaginations of some most influential couturiers of the twentieth and twenty-first centuries. Christian Dior *haute couture* in 2002 was inspired by the color ► [palette](#) of Malevich painting.

Simultaneous Contrast and Sonia Delaunay

In the 1920s, abstract painting inspired a variety of fabric designs, mainly based on the simultaneous contrast effect, by the successful designer and artist Sonia Delaunay [1]. Married to Robert Delaunay and friend of artists such as Mondrian, Arp, Vantongerloo, and Kandinsky, she was a member of the contemporary artistic avant-garde in her own right. It was her own abstract paintings that she translated into rhythmic designs composed of squares, lines, circles, diagonals, and color planes. In all, Delaunay created over 2,000 of these fabric designs, around 200 of them produced especially for the fashion house Metz & Co in Amsterdam.

Surrealism and Elsa Schiaparelli

Fashion designer Elsa Schiaparelli, Coco Chanel’s main rival in the 1920s and 1930s, produced clothing and hats heavily influenced by Surrealism [2]. Her sweaters incorporating knitted ties or sailor collars were a sensation, and she worked in close cooperation with artists such as Salvador Dalí and Jean Cocteau. An example of her work with Dalí is her famous lobster dress.

Coco Chanel and Japanese Art

The designer’s passionate interests inspired Coco Chanel’s fashions [3]. Her apartment and her clothing followed her favorite color ► [palette](#), shades of beige, black, and white. Elements from her art collection and theatrical interests likewise provided themes for her collections. The ornament of the dress, in both pattern and color palette, resembles the Asian lacquered screens which the designer loved and collected. In convergence with the Art Deco line, the modernist impulse was married with pure form and Japanese potential.

Neoplasticism and the Bauhaus

Piet Mondrian changed the face of modern art. His influence extends to painting, sculpture, graphic design, and fashion. In search of plastic harmony, he introduced a universal language of shapes and ► [primary colors](#) that goes beyond the painting; Mondrian was the central and most famous figure of the De Stijl movement. This style was baptized as neoplasticism and intended to achieve real objectivity by releasing the work of art from its dependence on the momentary individual perception and temperament of the artist. Yves Saint Laurent has created his famous dress with Mondrian’s color composition. The color in fashion design was developed by the school of Bauhaus and was also very enriching and interesting [4]. The relationship between form and color within the framework of visual perception was defined starting from the color theories of Kandinsky, Klee, Itten, and Albers in this school.

Op Art, Minimalism, and Pop Art in Fashion

Since the Second World War, there has also been frequent interaction between art and fashion. In the 1950s, Karel Appel produced signed fabric

designs; in the 1960s, the Bijenkorf department store sold dresses inspired by pop art, and since then the emergence of minimalist art has given rise to a widespread taste for sober, often asymmetrical designs. For instance, Jean-Charles de Castelbajac was inspired by Andy Warhol and his pop art *Campbell's Soup* painting. Victor Vasarely, Yvaral, and other representatives of optical art, as well as Friedensreich Hundertwasser's art, continue to influence modern fashion design and modern life [5].

In 2007, Christian Dior designed a unique piece, hand painted and enhanced with spectacular embroidery, Manteau Suzurka-San. Dior *haute couture* was inspired by *The Great Wave of Kanagawa*, emblematic work of the Japanese artist Hokusai. Focusing on the relationship between art and creations of the house Dior, it is possible to say that the original works have been in one way or another influenced by different artists. Certain highlighted artworks influenced not only the collections *haute couture* and *pret-à-porter* but also the unique world of fine jewelry, perfumes, and accessories. Because they reflect light and velocities, colors and shapes of the paintings of Sonia Delaunay emphasized the dancing model dressed in her parade by Ungaro Fall-Winter 2003–2004. Yves Saint Laurent revolutionized fashion and gave women the freedom of movement that has inspired artists, poets, and painters. “The profession needs an artist to exist,” he said. He loved painting and painters such as Matisse, Mondrian, Braque, Picasso, and Van Gogh. Saint Laurent began in 1988 with Georges Braque, whose famous birds seem to fly stuck to the bride's dress. Then, he designed a jacket inspired by *Iris* of Van Gogh. It took 800 hours to sew the whole Van Gogh. Flakes, tubes, seed beads, and ribbons were all embroidered by hand to make the effects and lighting of the canvas. Yves Saint Laurent influenced in some way other couturiers. For instance, stylist Erin Fee has been inspired by flowered textile design and some kind of “camouflage” for his fashion collection. Jean-Charles de Castelbajac, on the other hand, brings a joyful color palette from BD art graphics. Nowadays,

fashion designs have increasingly been regarded as autonomous works of art. Some creations by designers such as Viktor & Rolf now go so far in that direction as to be scarcely wearable at all. Viktor & Rolf spread their cutup couture in the magazine *Dazed and Confused*.

Tactile Color and Haute Couture

Nowadays, the collaboration between artists and fashion designers continues. The personal artist's inspiration comes from tactile painting. Jean Marie Pujol, couturier who worked with Dior and Yves Saint Laurent, designed several dresses to be painted by Larissa Noury as a means to perpetuate the art-and-fashion marriage [6]. With this personal style, a series of hand-painted dresses were created and presented during the exhibition at Faubourg's gallery in Paris, amid boutiques of Christian Dior, Jean Paul Gauthier, Chanel, and other creators of fashion.

Assimilation

Simone Gori
Department of Human and Social Sciences,
University of Bergamo, Bergamo, Italy

Synonyms

Bezold–Brücke effect; von Bezold spreading effect

Definition

Color assimilation is by some considered to be the opposite of the color contrast: the color is perceived in the direction of the hue of the surrounding color, whereas in color contrast the perceived color tends to be the complementary color. Assimilation can be experienced also in grayscale stimuli, and it is called lightness assimilation or brightness assimilation. In this case a gray is perceived lighter if it is close to a light object and darker if it is close to a darker object which is, again, the opposite of the simultaneous contrast.

Introduction

According to a naive physicalism, the physical stimulus should present a direct relationship with its mental correlate. Visual illusions (e.g., [1–3]) indicate, however, that physical manipulations of a stimulus do not directly determine the perceptual experience [4]. The existence of visual illusions has been already reported by ancient philosophers, and they were commonly considered counterintuitive singularities [5], which

demonstrate the active work of the sensorial system involved in the stimulus processing [6, 7]. It was proved that also non-human animals can experience visual illusions [8, 9]. An important sub-group of this illusion is the brightness illusion, and this also shows a similar counterpart in colored stimuli. It is often assumed that perceiving a surface as a source of light depends just on its physical radiant emission. However, the Persian natural philosopher Ibn Al-Haytham (circa 965–1040 AD), known as Alhazen, stressed the subjective nature of color sensation and argued in his description of the simultaneous contrast that color appearance is partly due to a mental process [10].

Simultaneous contrast can be described as follows: a gray target surrounded by a bright inducer that appears darker than its physical value. If the same gray target will be surrounded by a dark inducer, the results will be the opposite: the target will be perceived lighter than its physical value. The simultaneous contrast can be enhanced by blurring the boundaries of the inducer [11–14]. The simultaneous contrast is observed also in color stimuli where the color of the target tends to the hue of the opposite color of the inducer.

Assimilation Description

The brightness assimilation can be considered the opposite of the simultaneous contrast because under specific conditions a gray target will appear lighter when bordered by a brighter inducer and vice versa. The color assimilation is a similar phenomenon in which a colored target tends to be perceived as trending in hue toward that of the inducer color. Figure 1 shows a typical color assimilation display: the yellow background on the left is perceived slightly reddish, while the yellow background on the right is perceived as slightly bluish; however, the two yellows have identical reflectance functions. Figure 2 shows brightness assimilation: the gray background on the left is perceived lighter, while the gray background on the right is commonly perceived

Assimilation, Fig. 1 The color assimilation display: the yellow background on the left is perceived reddish, while the yellow background on the right is perceived bluish. The two yellows are physically the exact the same hue

Assimilation, Fig. 2 The brightness assimilation display: the gray background on the left is perceived lighter, while the gray background on the right is commonly perceived darker. The two gray values present the exact same luminance

darker; however, the two gray values have the exact same luminance. von Bezold [15] probably was the first to describe this effect in 1874. Based on the seminal observations by von Bezold, it seems that reducing the inducers' size and increasing their number (which implies increasing their spatial frequency and density together) will lead to a shift from simultaneous contrast to assimilation. Consequently, it seems clear that the physical variables responsible for this shift are the spatial frequency and the reflectance of the inducers. It is known, for example, that those two variables also affected the size perception [16]. Recently, it was demonstrated that even the perception of beauty is influenced by the spatial frequency [17]. However, the questions that remain open are: At which level of the brain processing are those variables interpreted in this specific way? And how does the visual system transform those variables in the final percept?

Possible Explanations for Assimilation

One approach to explain the assimilation is that bottom-up, peripheral mechanisms are sufficient to produce this percept. Assimilation could be indeed produced by the fact that the retinal input can be imagined as a blurry image; consequently, if the visual system will consider the retinal input of a display like the one in Figs. 1 or 2, the final percept will be in the direction of assimilation. However, considering how important is the cortical process in the final percept, it is hard to believe that at least in typically developed individuals the cortex will simply "accept" the retinal signal without any post processing in order to provide the final percept. Other proposals that consider the assimilation exclusively a bottom-up process are based on local averaging of luminance within large neurons' receptive fields. The receptive fields are small in the fovea and larger in the

periphery, and they also increase their size going up in the cortical hierarchy [18]. Specifically, two possible mechanisms have been proposed: a neuronal spatial integration [19] or neural weighted averages [20], suggesting that the primary anatomical site for assimilation could be spatially close but still outside V1. Both mechanisms may result in assimilation when the physical stimulus is a similar pattern to the one shown in Figs. 1 and 2. However, some predictions based on this explanation fell short in front of the lab tests. For example, DeValois and DeValois [21] suggested that stronger assimilation should be found for color in comparison with grayscale stimuli, because of the lack of lateral inhibition in chromatic receptive fields. However, the results by de Weert and Spillmann [22] showed that it was not the case.

Another approach that is not necessarily opposite to the bottom-up interpretation suggests that assimilation is primarily generated by more central mechanisms of visual processing, such as figure-ground segmentation [23, 24] and observer expertise [25]. It is also important to note that assimilation received interest based on the White illusion [26]. It has been suggested that assimilation depends on the existence of T-junctions that produce a perception of figure-ground segregation [27, 28]. T-junctions seem, for example, to affect also illusory motion [29]. However, this explanation was not supported by the lab test, which demonstrated that assimilation effects can also be seen in versions of White's display where T-junctions have been completely removed [30]. More recently, Soranzo et al. [31] supported the central mechanism explanation for assimilation by testing that in stroboscopic conditions. In 2010 Rude [32] proposed an intriguing computational neural model that includes the effect of the top-down attentional control in explaining the assimilation effect.

In summary, assimilation is an interesting phenomenon for which a convincing explanation that can keep all the experimental results under the same theoretical umbrella is still missing. However, several important steps were taken for the purpose of explaining how the brain interprets these patterns.

Advanced front lighting systems (AFS) – intelligent light; Bend light – cornering light; Glare-free high beam – adaptive driving beam (ADB); Matrix beam; Multi-beam; Pixel light; Segmented high beam

Definition

Automotive lighting in general includes all lighting functions installed on motor vehicles. While this includes rear and signaling devices, this chapter will focus only on front lighting systems. The main goal for automotive headlamps is to increase safety for drivers at night without glaring other traffic participants. For this reason, automotive manufacturers have constantly developed new headlamp technologies. Beginning with the historically and currently still relevant light sources for automotive front lighting systems such as tungsten halogen, HID, and LED light sources, different steps in the evolution of headlamp systems and their improvements are discussed in this paper. Going away from light sources, the historical evolution of intelligent headlamps and their light functions are discussed. Starting with the now widely available static and dynamic bend light, this chapter will work its way up to the latest headlight function – the road projection that is supposed to be market ready in 2020.

Aura

► Scintillating Scotoma

Introduction

Over the last years, the traffic density has increased significantly. With more and more vehicles driving on our roads simultaneously, one of the challenges for

car manufacturers is to ensure that traveling by car is as safe as possible. While this has led to improvements in the overall vehicle safety with additional active (e.g., emergency braking assistance) and passive safety features like improved crash stability, one key feature for safe driving at night is improved headlamps. Since the light situations between daytime driving and nighttime driving are completely different, during the day a global illumination from the sun generally lights the whole scene in front of the driver, enabling him to perceive all the necessary information for driving. At night the driver has to rely on artificial illumination. While in cities road illumination is present and allows for nearly the same overall light situation as during the day, on country roads or motorways, the driver has to rely on the headlamps of his vehicle. In order to make driving in those situations as safe as possible, headlamp manufacturers and car OEMs have developed and introduced new lighting technologies. The following sections will therefore introduce these new technologies. These sections will be split thematically into light sources and light functions.

Light Sources

In order to deliver the necessary amount of light for the driver to safely detect obstacles on the road, several new light sources were introduced to the mass market over the last decades. This

section will chronologically introduce those light sources, starting with the oldest and still most common one.

Tungsten Halogen Lamps

The oldest currently available light source for automotive headlamps is a tungsten halogen headlamp. Since this light source is the cheapest to produce, up until today it still holds the largest market share in automotive headlamps with over 80%. Figure 1 shows a standard H7 tungsten halogen light source for automotive headlamps on the left side and a luminance image of the same H7 light source on the right side. For better image quality, the tungsten halogen light source has been dimmed.

In a tungsten halogen headlamp, a small spiral-wound filament is used for light emission. Applying 12 V, as standard in automotive use, this filament is heated up to approximately 3000–3200 K which also represents the correlated color temperature (CCT) and starts to glow. Due to the thermal material boundaries and global regulations regarding tungsten halogen headlamps, their total luminous flux, the total light they emit, is limited to 1500 lumens. However, due to the nature of a so-called Planckian thermal radiator, most of the radiation it emits is not visible to the human eye, leading to a very low efficiency of only 20–25 lumens per watt.

Automotive Front Lighting System (Status 2020), Fig. 1 Left: H7 tungsten halogen light source. Right: Luminance image of the same H7 light source

High-Intensity Discharge (HID)

In order to increase the total luminous flux and the efficiency, high-intensity discharge (HID) light sources and headlamps were introduced in 1991. Compared to the filament in the tungsten halogen light sources, HID light sources use gas discharges to produce light. Since this requires a very high voltage, the 12 V from the car was not enough anymore, and a ballast is required in order to achieve about 10 kV. Nevertheless, HID headlamps have several advantages compared to tungsten halogen light sources, with the most important one being a higher luminous flux of up to 3200 lumens, a higher color temperature of around 4200–4500 K, and therefore an increased brightness perception for the driver and a much higher efficiency of up to 90 lumens per watt. The increase in total luminous flux also led to the introduction of two safety features in those HID headlamps that prevent other traffic participants from being glared. All headlamps, with light sources that produce more than 2000 lumens, require a headlamp cleaning device and an automated leveling system. The headlamp cleaning device avoids the possibility of dirt on the outer headlamp lens from scattering light into regions, where other traffic participants might be. The automated leveling system measures any vehicle inclination due to increased load in the trunk, for example, and automatically lowers the headlamp's aim.

However, since those two measures cost both weight and room in the vehicle, things car manufacturers never want to give up, 25-watt HID headlamps with a luminous flux of just below 2000 lumens, were introduced. Nevertheless, HID headlamps were soon replaced by their

successor and are currently not being used in new car generations anymore.

Light-Emitting Diodes (LEDs)

While light-emitting diodes (LEDs) are being used in general lighting since the early 2000s, it took until 2007 for the first headlamp to use LEDs for passing beam (Lexus LS 600h and Audi R8) and until 2010 (Audi A7, Mercedes Benz CLS) for a headlamp to solely utilize LEDs for all light functions like passing beam, driving beam, day-time running light, and turn indicator as well as several advanced lighting functions that will be explained in the next sections.

Compared to the thermal radiators (tungsten halogen lamps) and gas discharge lamps (HID), LEDs represent the third type of light source for automotive headlamps – the solid-state light source. The principle of solid-state lighting will not be explained here since this would go beyond the scope of this chapter but can be found in Ref. [1].

One of the main challenges when using LEDs as a main light source is the relatively low luminous flux of only around 1000 lumens – only a third of what an HID headlamp can produce. Due to this limitation, modern headlamps use several single LED chips for their light functions. As an example, the light module for low and high beam is shown in Fig. 2 with a photo of the layout on the left side and a luminance image on the right side. For measurement reasons, the LEDs in the luminance image on the right side are dimmed down to 1%, and only the passing beam LEDs are switched on. The driving beam LEDs are in the center of the module.

Automotive Front Lighting System (Status 2020), Fig. 2 LED module for a modern headlamp with ten LED chips for passing (2×3 LEDs) and driving beam (1×4 LEDs)

The main advantage of LEDs however is the high efficiency of at around 80–100 watts per lumen (automotive grade LEDs); the long-term reliability of around 10,000 h, thus exceeding the lifetime of a vehicle which drives approximately around 6,000 h (300,000 km at an average speed of 50 km/h); and the high flexibility and the low required volume.

Light Amplification by Stimulated Emission of Radiation (Laser)

To further increase the viewing distance for drivers, car manufacturers such as BMW, Audi, and Jaguar Land Rover started using light amplification by stimulated emission of radiation (laser) diodes as additional light sources for the driving beam. Since the usage of a laser light source in a vehicle is accompanied by a high amount of safety regulations and a very complex setup, this is only used in addition to a base LED driving beam. The advantage of a laser light source is that it can reach much higher luminance values compared to LED, HID, and tungsten halogen headlamps since the light-emitting area is comparably small. This is then used to produce a small hot spot in the center of the driving beam to allow drivers a larger viewing distance.

Compared to LED high beam, this can lead to an increase of about 60% as indicated by Fig. 3 where the detection distances of a pedestrian like dummy next to the road are measured [3].

Due the high cost and effort involved in using a laser light source, these headlamps are currently only found in a very select number of vehicles, and this will therefore not be discussed any further.

Advanced Front Lighting Technologies

Similar to the advancements in the light sources, new advanced front lighting functions have been implemented and introduced to the public over the last two decades. Figure 4 shows a brief overview over the currently available headlamp features.

This section will then explain in some detail each lighting function and the resulting benefit from it.

Static Bend Light/Cornering Light

In 2002 the first additional light function that was introduced was the static bend light or cornering light. Usually this is implemented by an additional light module that illuminates very wide angles as shown in Fig. 5. The idea for this is that when turning into a junction, the usual light distribution will not illuminate the sides sufficiently in order to detect pedestrians or cyclists that are crossing the road. The static bend light will then activate at very low speeds (<30 km/h) depending on the steering angle thus illuminating the intersection better.

Automotive Front Lighting System (Status 2020), Fig. 3 Detection distances for a pedestrian next to the road for LED low beam (blue), LED high beam (red), and high beam with added laser module (yellow) [2]

Automotive Front Lighting System (Status 2020), Fig. 4 Chronological introduction of adaptive front lighting technologies since 2002 up to today

Automotive Front Lighting System (Status 2020), Fig. 5 Low beam and static cornering light

Dynamic Cornering Light

Only 1 year later, the dynamic cornering light was introduced. The issue with the “normal” passing and driving beam light distributions when driving through corners is that the illumination will always be tangential to the actual corner, making it difficult to detect objects on the outside of the corner. To solve this issue, Daimler, Hella, and Opel introduced the dynamic bend light. For this light function, the low beam module is able to be swiveled by up to about 15° using stepper motors, thereby illuminating the bend better. This is illustrated in Fig. 6, where a static low beam is shown in dark orange in the background and a dynamic bend light is shown in the foreground.

This motion is dependent on the speed the vehicle is going, the steering angle, and the implementation by the manufacturer. While this does solve some of the issue, one still existing problem is that the swiveling will only start once the vehicle is in the corner. Approaches where GPS signals were used to predict bends failed due to the inaccuracy of such systems, and the automotive industry is still working on better solutions.

High Beam Assist

One issue that was shown by Sprute [4] is that human drivers tend to underuse the driving beam. His study shows that driving beam was only used 29.5% of the drive’s duration, while the recorded

A

Automotive Front Lighting System (Status 2020), Fig. 6 Static passing beam (dark light distribution in the back) and dynamic bend light (foreground)

maximum potential for high beam driving is at 60.5%, therefore more than double. Since passing beam should only be used during nighttime when passing another vehicle or while driving behind another vehicle since the viewing distance is limited, this results in a severe safety issue.

A first solution for this issue was introduced by BMW in 2005 with the high beam assist. A vehicle equipped with this feature automatically uses the driving beam when possible. For this, a camera is placed behind the windshield, usually inside or right behind the rearview mirror, which checks the road ahead for oncoming or preceding traffic. Due to the camera-based nature of this system, humans are still better in judging, when a vehicle is approaching and could, especially in cornering situations, often react earlier than this system.

Adaptive Passing Beam

All previous systems are based around one standard passing beam light distribution. However, it is easy to imagine that this singular light distribution cannot be the optimal light distribution in all situations. For that, Hella and Daimler introduced the adaptive passing beam. Depending on the situation, a different light distribution will be loaded by the vehicle. Exemplary light distributions are:

- Motorway light: the cutoff line of the low beam is moved up to the horizon by 0.25° :

- The higher driven speed requires more viewing distance. At the same time, fore field illumination is not required anymore since the driver needs to focus on the far field. To activate this function, the vehicle needs to be on a driving more than 100 km/h.
- Bad weather light: the low beam is lowered and swiveled to the side of the road:
 - Due to the higher reflectance of the road when wet, oncoming traffic could perceive more glare. At the same time, the darker road makes it more difficult for the drivers to orientate themselves on the road. To counter that, lowering the passing beam and swiveling it to the side increases the illumination of objects next to the road, thereby enabling the drivers to orientate themselves there. The intensity of the headlamp on the inner road side may be reduced as well to lower the glare potential for oncoming traffic.

Examples of these light distributions are shown in Fig. 7.

Headlight Range Control

While the highway light as introduced in the section above already bridges the gap between passing and driving beam slightly, this is still a digital selection between three levels of viewing distance. To achieve even better results, a headlight

Automotive Front Lighting System (Status 2020), Fig. 7 Adaptive passing beam light distributions. Bad weather light, normal passing beam, and motorway light

Automotive Front Lighting System (Status 2020), Fig. 8 Illustrated glare-free high beam light distribution (left) for an oncoming vehicle with passing beam (right)

range control was proposed in 2009. Again a camera detects, if other vehicles are on the road in front of the vehicle, and now also finds the exact position of head- or taillights. A stepper motor is now able to put the cutoff line of the low beam directly under the position of the head- and taillights of the approaching or preceding vehicle.

Glare-Free High Beam

The next and current step in evolution focusing on the viewing distance of the driver by optimizing the high beam usage is the so-called glare-free high beam. This system, introduced in 2010 by Volkswagen, enables the driver to use high beam at nearly all times when driving on country roads or motorways. Again a camera detects if and where other vehicles are. Instead of switching from driving beam to passing beam now, a shadow is inserted into the driving beam light

distribution to mask out other traffic participants. As illustrated in Fig. 8, this leads to light being sent to the sides of oncoming or preceding traffic, enabling the driver to much higher viewing distances.

The *THM, University of Applied Sciences, Gießen* has shown that the detection distances of objects beside the road with glare-free high beam can be increased by a mean of 32 m on average [5]. *Zydek* shows that for the detection of human-like figurines, the detection distance with passing beam is at 88.4 m, at 141.3 m with driving beam, and at 120.4 m with glare-free high beam, thereby closing the gap between the two basic light functions. *Zydek* also shows that the glare level perceived by oncoming traffic when driving with glare-free high beam is not significantly different from passing beam in any situation [12].

Technologically, this function can be implemented in two different ways. A mechanical solution uses a

sliding aperture to create a shadow in the driving beam light distribution. With the emerging of LEDs as light sources and their previously mentioned high flexibility, an electrical solution, where single LEDs are used to create single areas in the light distribution, was introduced as well. Simplified speaking, single LEDs are turned off to create the necessary shadow in the light distribution. LED-based glare-free high beam solutions are available with different number of LED segments, starting as low as 4 segments per headlamp and currently going as high as 82 segments per headlamp. However, different companies have already shown prototype solutions with thousands of segments per headlamp [6].

Both solutions come with advantages as well as with disadvantages. The mechanical solution is only capable of creating a single shadow. However, by using a modular approach in both headlamps, the size of this shadow is flexible. Using single LEDs, on the other hand, enables the car manufacturer to create multiple shadows; however, the size of these shadows is always limited by the size of the segment each LED produces. Another advantage of the electrical version over the mechanical one is that no moving parts are required thus increasing the reliability.

Marking Light

All new light functions so far focused on bridging the gap between passing and driving beam. A different approach was presented by BMW in 2011. Instead of delivering as much light as possible, the approach here is to use a small concentrated light spot to highlight important areas. In order to do so, an infrared camera is used to detect

pedestrians or animals beside or on the road at distances where the human eye is not able to do so. A small LED spot is then switched on for illuminating the object. In order to illuminate the target, this light spot is moveable on at least one axis by stepper motor. Schneider shows that this approach actually leads to better reaction times when detecting objects compared to driving beam [7]. However, this approach reintroduces moveable parts and requires additional hardware such as a night vision camera.

Road Projection

The latest addition to intelligent headlamp features is “road projections” where symbols or markings are projected into the low beam area. This feature is used to provide the driver with an alternative to a head-up display by providing simple information or warning signs directly onto the road as an additional way of conveying information to the driver similar to a head-up display. Additional features include the possibility to mark the width of the vehicle when driving through narrow road sections such as road works.

In order to do so, a digital mirror device (DMD) by Texas Instruments, known for its use in home theater projectors, which is able to produce millions of individually addressable pixels, is set into the headlamp as well and illuminated with high-power LEDs. Similar to the technology in conventional projectors, small mirrors reflect the light either onto the road or into a “light trap.” Controlling these mirrors, different symbols can be displayed on the road as shown in Fig. 9 [9].

Automotive Front Lighting System (Status 2020), Fig. 9 Symbol projection as presented by Daimler in their digital light concept [8]. (© 2019 Daimler AG. All rights reserved)

While one concern with this technology was that other road users might be distracted or even misinterpret these projections as signals for them, studies have shown that the projections are only visible from the driver's position and other road users don't even perceive them, let alone think they are addressed at them [10, 11].

[Autonomous vehicles – automated vehicles](#); [AV](#); [Highly automated vehicles](#)

Definition

Lighting systems for autonomous vehicles have completely different requirements when compared to the traditional automotive lighting systems of today. This chapter will focus on the changes necessary for vehicle lighting with the

introduction of autonomous or highly automated vehicles. While the current lighting systems for daily use are intended to enable the driver to safely steer the vehicle at night, an autonomous vehicle does not have a driver that needs to be able to view the road ahead. However, the necessity for lighting systems is still given since autonomous vehicles heavily rely on cameras that need light to function properly. Additionally, new studies show that the majority of people would like some kind of communication between autonomous vehicles and other human road users. Realizing these communication devices with light is one of the key challenges for the future.

Introduction

Over the last couple of years, more and more vehicles with highly automated functions have been introduced to the market. Starting with lane assist up to automated driving on certain types of road, the trend clearly shows that within the next years, fully automated vehicles will be part of our traffic environment.

While automotive lighting up until now focused mainly on the task of delivering light for the driver, to ensure safe driving, as well as a rudimentary signaling to other traffic participants with braking lights and turn indicators, lighting for automated vehicles will not have “drivers” as known today, and therefore the focus on lighting will shift. Two major areas are already in development by car manufacturers as of today. First of all, signaling has one of the highest priorities. With different approaches, car manufacturers are trying to communicate with other traffic participants in order to minimize misunderstanding, increase traffic flow, and even reduce the chance of accidents involving automated vehicles. The second large area of interest is lighting for the passengers. With no driving task, riding in an automated vehicle opens up the possibility for the passengers to pursue other tasks, ranging from relaxing or even sleeping to a mobile office. Developing smart interior lighting that suits those cases and puts the passenger and his task in the focus is the second big challenge for automotive

original equipment manufacturers (OEMs). Furthermore, all automated vehicles rely on several sensors, from cameras to RADAR and LIDAR sensors. Optimizing front lighting for those sensors to perform as good as possible even during the night is another big challenge when talking about lighting systems for automated vehicles.

This chapter will start by explaining the different levels of highly automated vehicles and the issues arising with highly automated vehicles driving in mixed traffic with other human road users (HRUs). The next section will then put emphasis on the different possibilities of using light for communication with other HRUs. The third section will explain the current development of interior human centric lighting for automated vehicles before the last section focuses on optimizing light for sensors.

Lighting for Highly Automated Vehicles

In order to discuss the different needs for lighting on automated vehicles, the first section will shortly introduce the different types of automated vehicles and motivate the need for communication devices on these automated vehicles.

Different Levels of Automated Vehicles

The Society of Automotive Engineers International (SAE International), a US-based standard developing association, has defined different levels of automated driving ranging from level 0 to level 5 (see SAE J3016 for reference). Level 0 describes vehicles with no assistant system. The driver performs all dynamic driving tasks (DDTs). Level 1 vehicles incorporate driver assistance features; level 2 vehicles have partial-automated driving features. Only level 3 and above vehicles can perform full DDTs. Level 3 vehicles can drive automated under certain conditions but still require a user to be able to take over; level 4 vehicles can perform automated driving under some conditions but do not require a driver to take over under these situations. Level 5 vehicles are vehicles with full driving automation. All these levels are summarized in Fig. 1.

Autonomous Vehicle (AV) Lighting Systems, Fig. 1 Different levels of automated vehicles according to SAE J3016. (©2019 SAE International. All rights reserved)

When referring to highly automated vehicles from now on, level 4 or level 5 vehicles are meant.

Reviewing exemplary traffic encounters, like a pedestrian crossing a road in front of a vehicle, it becomes obvious that some sort of communication between the driver of the vehicle and the pedestrian, while not absolutely necessary, is certainly helpful for the pedestrian.

Now please imagining a newly introduced automated vehicle without a human driver in the same situation. While the pedestrian looks to the approaching vehicle, the passenger may not be paying attention or even be in the vehicle. While this might not lead directly to a dangerous situation, this might leave the pedestrian wondering and confused about the next actions of the automated vehicle.

This combined with the increase in reported accidents involving automated vehicles over the last years leads to a decrease in trust into automated vehicles [1]. Openly communicating in an easy to understand way what the next intentions of the vehicle are could help increase the trust and acceptance toward automated vehicles [2].

Communication Strategies for Automated Vehicles with Human Road Users

In this section, the different possible strategies for light-based communication between highly automated vehicles (AVs) and HRUs are being explained. For this, the communication approach is split into different groups. The first section is dedicated to display-based communication where symbols, numbers, or even text is displayed on the

Autonomous Vehicle (AV) Lighting Systems, Fig. 2 Display integrated into a highly automated vehicle by Daimler [3]. (© 2019 Daimler AG. All rights reserved)

outside of the vehicle. The second section discusses light stripes before the third section introduces road projection as the last means to send messages from the AV to the HRU.

Display-Based Communication

When thinking about communicating between an AV and other road users, the most obvious idea is to use some sort of display. While this might not necessarily mean a high-resolution LCD or OLED panel that is wrapped around a vehicle, prototypes using LED matrices as means of integrating and displaying complex messages have been presented to the public by different companies. Figure 2 shows an example by Daimler of integrating a small display into the area of the grill for an AV.

While written text as shown in the example by Daimler is only feasible at short distances, larger, easier to understand symbols similar to traffic signs might be used for larger distances as well. However, these symbols and texts need to be universally understandable and intuitively designed.

Light Stripe-Based Communication

A different approach, shown, for example, by Ford and Nissan [4, 5], is the possibility to use simplified signals by implementing different light stripes around the vehicle. This is shown in Fig. 3 where a light stripe is implemented around the test vehicle.

By using different colors or animations on these strips, different messages such as “driving autonomously” and “I have seen you” or driving intentions “waiting,” “accelerating,” and “stopping” could be displayed. These animations might include blinking, swiping, or “loading bars.”

Projection-Based Communication

While both display- and light stripe-based communications require the HRU to look directly at the vehicle in order to perceive the message from the AV, projection-based communication provides the opportunity to send information in front of the HRU, thereby enabling communication even with distracted HRUs. In contrast to that, different environmental conditions, such as road surfaces, can have a major influence on the projection visibility. The technological basis for this has already been shown by Daimler in their Maybach’s S-Class. As described in the chapter ▶ “Automotive Front Lighting System (Status 2020)”, a DMD-based imaging device can be placed inside a headlamp to allow for detailed (megapixel) images to be projected onto the road. While the section in ▶ “Automotive Front Lighting System (Status 2020)” describes the use-case similar to the one of a head-up display, highly automated vehicles could use the same technology to project information for other road users onto the road. An example for this is again provided by Daimler in the form of the F 015 prototype [6]. As shown in

Autonomous Vehicle (AV) Lighting Systems,

crossing in front of the vehicle is safe [7]. (© 2019 Daimler AG. All rights reserved)

Fig. 4, the vehicle is capable of projecting a crosswalk for a pedestrian as a sign for the HRU that crossing the road in front of the vehicle is safe.

Light for Sensors

As mentioned in the introduction and as described in more detail in the chapter ► [“Automotive Front Lighting System \(Status 2020\)”](#), front lighting so far has been focused on increasing the detection distances of drivers while at the same time minimizing glare for other traffic participants. With the introduction of level 4 and level 5 vehicles, the vehicle can operate without any driver in them. In order to do that safely, a large sensor array is used

in order to measure the surroundings of the vehicle at all times. As an example the sensors of the Mercedes-Benz Intelligent Drive “Bertha” are shown in Fig. 5.

As shown by Daimler, a large area of the traffic space is covered by cameras either in single camera use, indicated in blue, or by stereo camera systems, indicated in green. Only small areas but large distances are covered by radar. While radar is not influenced by the surrounding light conditions, cameras are highly dependent on other light sources.

Using headlights and optimizing their light distribution to increase the performance of the

cameras now becomes one of the major developing points, and it has already been shown that using high-performance headlamps increases the confidence of object detection significantly [9].

Interior Lighting for Automated Vehicles

While the lighting systems discussed so far all focused on exterior lighting, new interior lighting

systems will emerge as well for AVs. Since none of the passengers needs to focus on driving and thereby detecting objects or keeping the vehicle safely on the road, optimizing the interior light on the new tasks that are being performed inside of the vehicle becomes a higher priority. While this sort of lighting has already been a major research point for home and office lighting [12], interior

lighting for vehicles has been scarcely researched up until now.

Daimler has presented prototypes and concepts that could be used in current vehicles as well. A high intensity light panel (Daylight+) is introduced in their concept vehicle ESF as part of the all-round driver safety (Fig. 6).

The goal by Daimler is to increase the brightness inside the otherwise comparably dark driver's cabin, thereby increasing the driver's alertness [10]. Audi increased the individualization for passengers by introducing "Matrix Interior Lighting Systems" to the market. Similar to the glare-free high beam systems discussed in the chapter ▶ "Automotive Front Lighting System (Status 2020)", individual LED segments are used for each passenger allowing them to customize the direction and the intensity of their individual lighting system [11].

However, compared to the state of the art in Human Centric Lighting (HCL) in home and office applications, these lighting systems are still at the beginning. In those applications light is intentionally used to increase the user's well-being, mood, and even health [11]. This can be done by simulating natural light – our body synchronizes with the natural sunlight, and sitting in dark offices with artificial light sources can get our body out of that natural rhythm which in turn can have negative effects on our health – or by finding the right lighting conditions for the task that is being performed at the moment. The right lighting condition can have a major effect on performance and productivity [11].

Further Remarks

While first automated vehicles are already on our roads, all previously discussed lighting systems are still in development. Especially using light as a means of communication between an AV and a HRU is still being investigated in numerous ways. The presented methods all include advantages and disadvantages that still need further research. Rasouli gives an overview about conducted studies and research methods [7]. Additionally to that, no regulatory basis for

these kinds of exterior lighting system has been released as of today since the research on what kind of signal in what kind of situation and by what kind of technology needs to be presented is not fully concluded.

Avicenna, Abū ‘Alī al-Ḥusayn ibn ‘Abd Allāh ibn Sīnā

Eric Kirchner¹ and Seyed Hossein Amirshahi²

¹Kirchner Publications, Leiden, The Netherlands

²AUT Textile Department, Amirkabir University of Technology, Tehran Polytechnic, Tehran, Iran

Iran’s Abu ‘Alī al-Husayn ibn ‘Abd Allāh ibn Sīnā (Latinized name: Avicenna) was a Persian polymath and probably the most influential natural philosopher in all of Islamic history [1]. He was born around 980 AD near Bukhara (present-day Uzbekistan) and died in Hamadan (Iran). Already at the age of 16, famous physicians worked under his direction, and at the age of 18, Ibn Sina mastered the contemporary knowledge of the various sciences [2]. His massive *Qanun fi-‘l-tibb* (Canon of Medicine) would be the main medical text in the East and West until the seventeenth century.

The *Kitab al-Shifa* (The cure [of ignorance]) is an equally immense four-part encyclopedia on mathematics, physics, and metaphysics [3, 4]. For several centuries this would be the main text on Aristotelian natural philosophy. Here, Ibn Sina

displayed his Aristotelian sympathies mainly by refuting alternative theories. For theories on light and color, this meant that Ibn Sina rejected the so-called extramission theories advocated by Ptolemy and Euclid. Ibn Sina gave good arguments why it is absurd to assume that vision occurs by visual rays emerging from the eye. Instead, Ibn Sina explained vision in terms of forms transmitted from the visible object to the eye (i.e., by intromission). In this respect, he followed Aristotle just like Ibn Rushd [5]. It would be Ibn al-Haytham, a contemporary of Ibn Sina, who would formulate a successful fusion of the optical theories of Ptolemy, Euclid, Galen, and Aristotle. It would be an intromission theory.

The *Kitab al-Shifa* contains a full chapter on color [6, 7]. In chapter 4 section 3, Ibn Sina was the first to break with the Aristotelian notion that all colors can be ordered along a one-dimensional line, writing:

... the fact that white gradually passes to black by three paths. The first is via pale [...], at first it progresses to pale, from there to grey, and continuing in this manner until black is obtained [...]. There is also another path proceeding [from whiteness] toward red, and from there to red brown, thereafter to black. The third path is the one going to green, from there to indigo, thereafter to blackness. [4, 7]

Thus, Ibn Sina introduced what in modern terms would be called a two-dimensional color order (cf. the illustration above) [8]. It would become known in Christian Europe as well, for example, through its inclusion in the *Speculum maius* from Vincent de Beauvais (1244) [7]. Ibn Sina's texts on color were also widely discussed in the Islamic world. When more than two centuries after Ibn Sina's death a student of the astronomer al-Tusi formulated questions about Ibn Sina's color ordering, al-Tusi further elaborated on this theory [9].

In his commentary, Ibn Sina also criticized the Aristotelian ideas on color mixing. For example, he disagreed with the Aristotelian tradition that claimed that green is composed of red and purple. According to Ibn Sina, a composition of red and purple does not produce green because from mixing red with purple, a color is produced that is brighter than purple but more purple than bright

red. Instead, according to Ibn Sina green is formed by a mixture of yellow, black, and indigo blue [10]. Further, Ibn Sina made a clear distinction between the brightness of a light source (*lux*, in the Latin translation of Ibn Sina's work) and the "splendor" shining from an object (*lumen*) [11].

Finally, Ibn Sina was highly critical about what was known about the cause of the rainbow. He wrote that he was "not satisfied with what our friends the Peripatetics [i.e., Aristotle and his followers] have to say about the rainbow." He continued by reporting some of his observations that cannot be explained by that theory, only to conclude that he himself also had nothing to add, except by a suggestion that the cause of these colors might be inside the eye of the observer [5].

Bartleson, C. James

Robert W. G. Hunt
Department of Colour Science, University of
Leeds, Leeds, UK

C. James Bartleson was an American color scientist who made very important contributions to colorimetry and visual science.

Bartleson graduated as an Associate of Photographic Science at the School of Photography at Rochester Institute of Technology (RIT), Rochester NY, USA, in 1951. He received a Ph.D. at the City University, London, England, in 1977.

After high school, he enlisted in the marines and served as a frogman using photography. After his discharge in 1948, he spent a year doing freelance aerial photography and then enrolled in the School of Photography at RIT to obtain his degree of Associate of Photographic Science in 1951. There followed a 3-year period working on the new Ansco Plenachrome system at the Pavelle Color Corporation in New York City.

In 1952, he moved to Rochester, NY, to start a career with the Eastman Kodak Company. His first assignment was in the Color Control Department under Ralph Evans but his flair for research was noticed and in 1957 he moved to the Physics Division where he started his research on color and tone reproduction which led to the publication of a series of very significant papers, one of the most outstanding, in 1967, coauthored with Ed Breneman, being on the effect of light and dark surrounds on apparent contrast. His papers attracted various awards, and he was one of the first recipients of the C.E.K. Mees Award. He was also author, coauthor, or editor of several books, including the five volume series on "Optical Radiation Measurements." He was also much sought after as a lecturer, and his award of the British Color Group's Newton Medal was accompanied by a masterly presentation.

In 1967, his outstanding reputation led him to be chosen to establish a research facility for the MacBeth Company, later the MacBeth Color and Photometry Division of the Kollmorgen Corporation, in Newburgh, NY.

When his time at Kollmorgen came to an end in 1974, the following year, at the then age of 45, he enrolled in the School of Ophthalmic Optics and Visual Science at The City University, London, England, and obtained his Ph.D. in 1977. With typical enthusiasm, he constructed an ingenious apparatus for studying the effects of adaptation on perception, and the resulting thesis was of outstanding quality.

He then returned to Rochester, NY, to resume his career at Kodak, where he soon established a reputation as a most valuable consultant for other members of the staff.

He was the President of the AIC (Association Internationale de la Couleur) from 1978 to 1981, reviving it from a moribund state, and he took part in several committees of the CIE (Commission Internationale de l'Éclairage).

His main interests included optics, vision, photometry, colorimetry, color perception, color applications, and color photography. His leisure interests also included photography and travel.

Batik

Traci A. M. Lamar
Wilson College of Textiles, North Carolina State University, Raleigh, NC, USA

Synonyms

[Resist printing; Wax-resist dyeing](#)

Definition

Batik is a process for creating patterned textiles by applying wax in defined areas to form a dye resist, then subsequently dyeing the fabric. A textile created using this process is also referred to as a batik.

Background, Process, and Aesthetic Properties

There is no general agreement in the textile coloration field regarding where the practice of batik originated. Early examples of batik have been

found in India, Central Asia, the Far East, and the Middle East [1]. The techniques and tools used to accomplish batik varied from region to region and still do. In many parts of the world batik is an important component of the cultural heritage and this is reflected in the often symbolic colors, motifs, and designs used in the traditional batiks. Many sources identify the term batik as an Indonesian word deriving from the Javanese *amba*, meaning “to write” and *titik*, meaning “dots.” Creating hand-drawn, detailed batiks is an exacting process and a lengthy one. Indonesian batik has long been, and continues to be, widely regarded as reflecting the most advanced practice and the highest standards, especially on the island of Java. In 2009 Indonesian batik was inscribed to UNESCO’s Representative List of the Intangible Cultural Heritage of Humanity [2]. Therefore, the methods, tools, and examples for Indonesian batik are used to illustrate the batik process.

Batik is typically characterized as a form of resist printing, or resist dyeing, due to the pattern being formed during the coloration process by an applied dye resist. In the batik process, hot liquid wax is applied to a textile to create areas of resist that prevent dye penetration and areas that retain their original color during subsequent dyeing.

The textiles used for Indonesian batiks are typically finely woven cotton. To begin, the fabric is stretched across a frame made of wood or bamboo called a “gawangan” [3] to provide support. For large batiks, the fabric may be stretched across a padded table instead. Paraffin wax, beeswax, or a mixture of these is commonly used in the batik process. Resin may be added to the wax. The specific desired effect defines the best wax blend to use. Indonesian batik traditionally uses beeswax, and paraffin wax is mixed in to enhance the cracking effect. When fresh, the wax is translucent and yellow but may look dark or brown after being reused many times [4]. The tjanting or canting is a traditional tool used to apply wax in the batik process (Fig. 1). The tjanting consists of a copper cup to hold the hot wax attached to a bamboo handle.

The copper cup has one or more spouts through which hot wax can flow. The tjap or cap, a block comprised of strips of cut copper shaped into

Batik, Fig. 1 A batik tjanting for applying wax by hand drawing. (Image credit: Gregg Museum of Art & Design, Raleigh NC; Gift of Helen S. Underhill, 2001.035.031)

detailed patterns and soldered with a handle on the back, can be used to stamp hot wax onto the textile. The tjap allows wax to be applied much more quickly, and also for the easy creation of repeating patterns. The tjap can also be used with the tjanting for quicker wax application, and is especially useful for large batiks. Some batik artists also use a tool made by wrapping fabric around a stick to brush wax onto large areas of the textile. In the highest quality batiks, wax is applied to both sides of the fabric guaranteeing batiks with clean, sharp designs. Waxing both sides of the fabric lengthens the process of creating a batik, so it is not always done. Maintaining a constant wax temperature is also important to the quality of the batik because wax temperature impacts how much the wax runs when applied.

After the application of the wax resist (Fig. 2), the textile is dyed. The resist created by the wax may crack during the coloration step, allowing dye to penetrate the waxed areas and creating a crackled effect in those areas. Prior to dyeing, cracking can be increased if desired by folding, twisting, or otherwise manipulating the cloth after the wax has cooled and hardened. Traditional Indonesian batik uses natural dyes, although in areas of Indonesia use of synthetic dye has shortened the dyeing process and contributed to richer and more varied colors than the traditional indigo blues, browns and reds. The initial dye bath contains the lightest color needed in the final design, and waxed areas of the fabric resist dye penetration remaining white. The dyed fabric is then washed. After cleaning, waxing is repeated but

Batik, Fig. 2 Full view (*top*) and detail view (*bottom*) of batik fabric before dyeing, with wax designs still on the fabric. The design was created by both hand drawn and stamped wax application and includes traditional

Indonesian wayang puppet figures. (Image credit: Gregg Museum of Art & Design, Raleigh NC; Gift of Dorothy H. Pope, 1997.008.002)

Batik, Fig. 3 Full view (*top*) and detail view (*bottom*) of batik with design featuring puppet-like figures similar to undyed waxed fabric in Fig. 2. (Image credit: Gregg

Museum of Art & Design, Raleigh NC; Gift of Dorothy H. Pope, 1997.018.001)

this time areas to remain white and areas to remain the color of the initial dyeing are waxed. The fabric is then placed in a second dye bath containing the next lightest color in the design.

This process of waxing, dyeing, and washing is repeated until all colors of the design have been achieved and a multicolored image is revealed on the fabric. When the dyeing process is complete,

Batik, Table 1 Aesthetic properties of batik

Cracking or veining	Dye penetration of small cracks in the wax resist during dyeing creates veined patterns in the batik when the wax is removed
Flowing, liquid quality	Lines and details with a flowing, liquid quality are found in batiks, due to the hot, liquid wax being applied to create the design
Halos	In many designs, slightly darker or lighter halos are found around pattern motifs and lines
Saturated color	Because batik involves dyeing the textile, areas that are allowed to absorb dye are saturated through with color
Design on both face and back	Because wax is often applied to both sides of the textile, the batik motifs, lines, and patterns are created on both sides

Batik, Fig. 4 Batik from Java, Indonesia with tjap stamped motifs and traditional dotted patterning. (Image credit: Gregg Museum of Art & Design, Raleigh NC; Anonymous gift, 1986.005.006)

all of the wax resist must be removed from the base fabric. This is accomplished through boiling the batik in water containing a detergent. Finally, the batik is rinsed and dried (Fig. 3).

Contemporary batik differs from traditional, more formal types. Batik artists use a variety of textile materials and may combine batik with other surface design methods such as etching or discharge printing. Contemporary batiks are created with traditional tools, nontraditional tools, and contemporary versions of traditional tools. For example, an electric tjanting allows contemporary artists to adjust the flow of the wax and the wax temperature to be maintained at a constant level, facilitating high-quality wax effects. Lawrence [5] identified five aesthetic properties characterizing contemporary batik, which are described in Table 1. Some of these properties can be seen in the Fig. 4 detail view. It is important to note that prevalence of and preference for veining in batik is culturally based, and cracking is traditionally undesirable in Javanese batik but quite valued in some other cultures.

Bayesian Approaches to Color Category Learning

[Ideal observer models of color category learning](#);
[Rational models of color category learning](#)

Definition

Bayesian approaches to color category learning formalize learning as a problem of Bayesian inference, requiring the learner to form generalizations that go beyond observed examples of members of a category. This formal framework can be used to make predictions about both individual judgments and how populations form color categories.

Color Category Learning

One of the challenges that children face as they acquire a language is discovering how words are used to refer to different colors. While human languages demonstrate variation in how they partition the space of colors, there are also clear regularities in the kinds of systems of color categories that are used [1, 2]. This raises two important questions: How might color categories be learned? And how might regularities in systems of color categories across languages be explained?

Learning color categories is an inductive problem, requiring learners to make an inference from labeled examples of colors to a full system of color categories. As in other domains of perception [3], an “ideal observer” model can be used to

explore the optimal solution to this problem. Let h denote a hypothesis about a possible system of color categories and d the observed data – a set of labeled examples (such as “This color is blue, and this color is yellow”). If learners represent the degree of belief in the truth of each hypothesis with a probability, $P(h)$, then the ideal solution to the problem of updating these beliefs in light of the data d is provided by Bayes’ rule:

$$P(h|d) = \frac{P(d|h)P(h)}{\sum_{h'} P(d|h')P(h')}, \quad (1)$$

where $P(h|d)$ (known as the posterior probability, in contrast to the prior probability $P(h)$) indicates the degree of belief assigned to h after observing d and $P(d|h)$ (known as the likelihood) indicates the probability of observing d if hypothesis h were true.

The sum in the denominator of Bayes’ rule ranges over all possible hypotheses and ensures that $P(h|d)$ is a valid probability distribution, summing to 1. The key idea behind Bayes’ rule can be obtained by ignoring this constant and simply inspecting the numerator: The new beliefs of the learner result from combining the previous beliefs, captured in the prior distribution $P(h)$, with the probability of the observed data under each hypothesis, expressed by the likelihood $P(d|h)$. The prior distribution captures the expectations of the learner, but also indicates which hypotheses are easy or hard to learn. A hypothesis that has low prior probability requires stronger evidence (in the form of a higher likelihood) to end up with a high posterior probability and so will be harder to learn. The prior distribution thus provides a way of encoding the perceptual or learning biases of the learner, favoring some hypotheses over others.

The Bayesian approach to modeling learning has proven successful in accounting for human behavior in a wide range of tasks [4]. In particular, Bayesian models have been used to account for how people learn new concepts and new words. Tenenbaum and Griffiths [5] presented an account of how people form generalizations from examples, such as inferring what other numbers might

belong to a set when told that the set contains 2, 8, and 64. Under this account, hypotheses correspond to possible sets of numbers, and the likelihood is obtained by calculating how likely it is that the examples would be observed if they were sampled at random from this set. Xu and Tenenbaum [6] showed that a closely related model captured how children learned nouns corresponding to sets of objects, such as determining the appropriate referent of words corresponding to “Dalmatian” or “dog.” These results suggest that a Bayesian approach might also be fruitful for explaining the acquisition of terms for color categories.

Dowman [7] presented a model that took exactly this approach, providing a Bayesian account of color category learning. In this model, the space of colors is reduced to a one-dimensional ring of hues. Each color category then corresponds to an interval on this ring, picking out a set of adjacent colors. Labeled examples of color categories are assumed to be sampled from the categories at random, with a small probability of an error taking place. This makes it possible to calculate the probability of any observed set of labeled examples for each candidate interval from which they might be drawn, providing the likelihood $P(d|h)$. Bayes’ rule can then be used to compute a posterior distribution over possible intervals for each color category. The probability that a color that has not previously been labeled belongs to that category is then obtained by summing the probability of all intervals that contain that color under the posterior distribution. Dowman demonstrated that this model made reasonable inferences for simplified versions of the systems of color categories from real languages, such as Urdu.

The predictions that Dowman’s model makes about learning of color categories have not been directly tested with human learners, but results in other domains and with other species provide support for this approach. As noted above, Xu and Tenenbaum [6] found that a very similar model accounted well for the generalizations that children made in learning novel words describing sets of objects. In addition, Jones, Osorio, and Baddeley [8] found that poultry chicks form

generalizations about colors in a conditioning task that is consistent with a model based on that of Tenenbaum and Griffiths [5].

Cultural Transmission of Color Category Systems

The results summarized so far indicate how Bayesian models might be used to explain learning of color categories. The same models also have the potential to provide insight into why regularities exist in the systems of color categories that appear across human languages. Dowman [7] explicitly had this goal in mind in defining his Bayesian learning model, which was used as a component in a simulation of the cultural transmission of systems of color categories. Dowman's aim was to investigate the consequences of cultural transmission of systems of color categories among a set of agents that used a realistic approximation to human learning. He found that cultural transmission by Bayesian agents produced systems of color categories with properties similar to those seen across human languages, providing a potential explanation for the source of those regularities.

Dowman's simulation of cultural transmission was an instance of a more general approach to exploring the origins of different kinds of structure in human languages, known as iterated learning [9]. In an iterated learning model, a set of agents each learn from some observed data and generate data that is observed by other agents. The simplest case is where the agents form a chain, with each agent learning from data generated by the previous agent and generating data that is provided to the next agent. Griffiths and Kalish [10] showed that when this form of iterated learning is carried out by Bayesian agents who all have the same prior, the hypotheses considered by those agents eventually converge to a distribution that matches the prior distribution. More precisely, the probability that an agent selects a hypothesis h converges to the prior probability of that hypothesis $P(h)$ as the chain gets longer.

The results of Dowman [7] and Griffiths and Kalish [10] raise an interesting question: Can the

regularities seen in systems of color categories across human languages be accounted for by cultural transmission producing convergence on a shared prior distribution? To explore this question, Xu, Dowman, and Griffiths [11] conducted an experiment in which human participants simulated cultural transmission by iterated learning. Each participant was given some examples of colors from novel categories and then asked to generalize to a larger set of colors. The generalization responses were then recorded and used to generate the examples that were seen by the next participant. Figure 1 shows examples of color category systems produced by chains of participants in this experiment. Each chain was initialized with data generated from a random partition of color space into labeled categories. The number of allowed categories varied across chains, ranging from two to six categories. Xu et al. [11] found that over time, the systems of color categories converged to forms that were consistent with the regularities seen across human languages [2].

These results support the idea that cultural transmission and perceptual or learning biases of the kind that might be captured by a prior distribution in a Bayesian model may be sufficient to explain the origins of cross-linguistic regularities in systems of color categories. However, much remains unknown about the precise characterization of the human prior distribution over systems of color categories and whether the structure of that distribution can capture cross-linguistic variation. One approach to this question was suggested by Carstensen, Xu, Smith, and Regier [12], building on the idea that languages are shaped by pressure for informative communication. Carstensen et al. [12] showed that the iterated learning experiment of Xu et al. [11] produced systems of color categories that become highly informative, in addition to becoming more similar to actual color category systems of human languages [11]. They concluded that cultural transmission with a bias toward informative communication may explain the constrained cross-linguistic variation seen in color category systems.

Carr, Smith, Culbertson, and Kirby [13] proposed an alternative explanation for these results.

Bayesian Approaches to Color Category Learning, Fig. 1 Examples of color category systems produced by chains of human learners in the iterated learning experiment of Xu et al. [11] (figure adapted from [11]). Each column corresponds to one cultural transmission chain with 13 participants (rows) and 2–6 categories. All systems are plotted against the World Color Survey stimulus palette [2], which contains 10 achromatic color chips and 320 maximally saturated color chips arranged by hue

(horizontal axis) and lightness (vertical axis). Each category is color-coded by its color centroid in CIELAB space and covers all the chips in the palette that were assigned to it. The chains were initialized with a random system, shown at iteration 0. Over time, the systems produced by the learners become more similar to actual systems across languages [11], capturing observed cross-linguistic regularities.

They argued that a human prior distribution over category systems is better characterized by a bias toward simplicity for learning rather than informativeness. Carr et al. [13] suggested formal definitions for a simplicity prior and an informativeness prior and then used these prior distributions for model simulations of iterated learning with Bayesian agents. They demonstrated that the simplicity model can produce structured category systems that are also highly informative, which may give an impression of a bias toward informativeness even in cases where it is not actually present. In addition, Carr et al. [13] tested these models on human iterated learning data and found stronger empirical support for a bias toward simplicity. Their results, however,

are based only on synthetic domains that are qualitatively different than color. Therefore, it remains unclear to what extent simplicity, informativeness, or possibly both, may characterize human biases involved in learning systems of color categories.

Bayesian approaches to color category learning can be used to explore questions about how children might learn how their language partitions the space of colors, why regularities are seen in systems of color categories across languages, and how color categories may evolve over time. However, many important questions remain open for future research. One fundamental question is how well Bayesian models can capture the generalizations that real human children make when

learning color categories. Another fundamental question for future research is how communication between two or more agents within a generation may influence the patterns that emerge in culturally transmitted systems of color categories. Communication is believed to play an important role in the cultural evolution of language [14], in addition to learning. Furthermore, it has been argued that systems of color categories evolve along an information-theoretically optimal trajectory of communication systems involving Bayesian agents [15]. This information-theoretic approach captures much of the regularities and variation seen in systems of color categories across languages, suggesting a potential theoretical link between communication and learning in Bayesian models of color categories.

a variety of non-hue senses, taking on predominantly hue sense during the Middle English period. *Purple* and *orange* were borrowed from Latin and Arabic with a hue sense from the beginning, and *pink* emerged sometime in the sixteenth century.

Definition

The Berlin-Kay theory of basic color terms maintains that the world's languages share all or part of a common stock of color concepts and that terms for these concepts evolve in a constrained order.

Basic Color Terms

In 1969 Brent Berlin and Paul Kay advanced a theory of cross-cultural color concepts centered on the notion of a *basic color term* [1]. A basic color term (BCT) is a color word that is applicable to a wide class of objects (unlike *blonde*), is monolexemic (unlike *light blue*), and is reliably used by most native speakers (unlike *chartreuse*). The languages of modern industrial societies have thousands of color words, but only a very slender stock of basic color terms. English has 11: *red, yellow, green, blue, black, white, gray, orange, brown, pink, and purple*. Slavic languages have 12, with separate basic terms for light blue and dark blue.

In unwritten and tribal languages the number of BCTs can be substantially smaller, perhaps as few as two or three, with denotations that span much larger regions of color space than the BCT denotations of major modern languages. Furthermore, reconstructions of the earlier vocabularies of modern languages show that they gain BCTs over time. These typically begin as terms referring to a narrow range of objects and properties, many of them noncolor properties, such as succulence, and gradually take on a more general and abstract meaning, with a pure color sense.

The development of English BCTs is typical [2]. The terms *red, black, white, gray, red, green, yellow, and brown* have roots that go back to Old English and before. All of them except for *red* had

The Original Berlin-Kay Theory

These considerations invite two questions. Are there similarities in the ways that different languages with the same number of BCTs carve up color space? Is the order in which languages acquire BCTs constrained? In their influential 1969 *Basic Color Terms* [1], Berlin and Kay answered both questions in the affirmative and proposed a sequence in which the number of BCTs in a language predicts what those terms would be. According to the scheme, a Stage I language will contain terms for black and white. In Stage II, these are joined by a word for red. In Stages III and IV, either a word for green appears, followed by a word for yellow, or else a word for yellow appears first, followed by a word for green. A word for blue arises in Stage V, followed by a word for brown in Stage VI. Thereafter, in Stage VII, words for pink, purple, orange, and gray appear in no particular order.

The World Color Survey and the Revised Berlin-Kay Theory

The 1969 sequence has been enshrined in many textbooks, but it has since been significantly modified and conceptually refined. The authors and their collaborators improved their methodology and greatly extended the scope of their samples with the 1976 *World Color Survey* (WCS) [3] published with analysis and interpretation in 2009, along with work by others, notably MacLaury's 1997 *Color and Cognition in Mesoamerica* [4]. For the WCS, Protestant missionaries from the Summer Institute of Linguistics collected data from 25 monolingual speakers of each of 110 unwritten minor and tribal languages from 45 different language families. Respondents

were asked to name 320 Munsell color chips of maximum chroma and 8 value levels in addition to 10 achromatic chips, presented in random order. After two such naming sessions, they were presented with a miniature version of all 330 samples arrayed in standard order and asked to pick out focal (best) examples of each of the named colors. The resulting dataset [5] permitted much more sophisticated statistical analysis, which broadly – but not completely – confirmed Berlin and Kay’s original conclusions. However, in the years between the appearance of *Basic Color Terms* and the publication of the World Color Survey, the original sequence was replaced by a substantially more complex developmental scheme, as well as a reconceptualization of what that development consisted in.

The original sequence was understood as a succession of encodings of basic colors in which a language would acquire a term for red, and a bit later yellow or green, then blue and so on. It soon became clear that this wouldn’t do, since in languages with fewer BCTs, the reference for each color term would encompass a correspondingly larger region of color space – a megacategory – so the addition of each new BCT should be understood as breaking up a megacategory into smaller categories. For instance, in a Stage I language with just two color categories, referring to one category as “white” and to the other as “black” is misleading, since the native category names extend across a broad range of hue samples. The more accurate gloss would be “warm/light” for the “white” category and “dark/cool” for the “black” category. In WCS notation, Stage I is represented as [W/R/Y, Bk/G/Bu]. In Stage II, the first megacategory breaks up, yielding [W, R/Y, Bk/G/Bu], and so on, culminating in Stage V, consisting of [W, R, Y, G, Bu, Bk]. The remaining BCTs appear in no fixed order.

A well-established basic megacategory in many North American and Mesoamerican Indian as well as some African languages is a “grue” term that covers the region that English speakers would separate into a blue and a green category. English, in turn, has its own megacategory. Modern Russian speakers break up our blue category with two BCTs: *goluboi*, light blue, and *sinji*, dark blue.

Constraints on Color-Category Formation

A fundamental question now arises. If the development of basic color categories is constrained in various ways, what are the bases of these constraints? One striking feature of the sequence is that as megacategories break up, categories whose foci lie close to the six elementary Hering colors get named before categories focused near the binary colors such as orange. Furthermore, the focal choices for each of these categories tend to cluster around average unique hue choices. Studies have found the variability of focal choices among the speakers of a given language to be substantially greater than the variability of average focal choices across languages with a comparable number of BCTs. This suggests that the elementary colors are perceptually salient for all language users, making them more likely to be named [6].

Alternative Explanations

An alternative view, first advanced by Jameson and D’Andrade [7], starts with the observation that the outer surface of the Munsell solid that was used in the collection of the WCS data is lumpy. Regions of high chroma are “mountains” of greater perceptual prominence than “valleys” of lower chroma in which the samples are less readily discriminable from their neighbors. This salience makes them more readily nameable.

Kay and Regier [8] constructed a CIELAB representation of the WCS Munsell samples and used them to define a dispersion metric. This enabled them to determine individual and group centroids for every category of each WCS language. They found a strong tendency of category centroids to cluster across languages. Subsequently, they used the same CIELAB representation to formalize and test the ideas of Jameson and D’Andrade [9]. Defining similarity and dissimilarity measures, they derived a measure of the “well formedness” of a language. By this they mean the extent to which the language maximizes the perceptual similarity of colors within a category and minimizes it across categories. Rotating

the data for each of the WCS languages around the lightness axis showed that in most cases the well formedness of the language was maximized at or very near 0° of rotation. They concluded that the irregularities in perceptual color space along with general principles of category formation could account for the organization of the WCS languages. Well formedness is not overly sensitive to the placement of category boundaries, according to this account, and permits adjustment by linguistic convention.

Other explanations for the Berlin-Kay structure take different approaches. Vantage Theory, offered by Robert MacLaury, is psychological, giving a role to individual perceptual-cognitive differences. By contrast, a theory advanced by Sergej Yendrikhovskij [10] maintains that the structure of color-category systems originates in the statistics of the natural environment. He developed a clustering model that predicted the location, number and order of color categories and tested the model with a database of 630 natural images. The clustering was consistent with the 11 basic color categories of Berlin and Kay. These theories of universal constraints are not necessarily incompatible, since they focus on different aspects of color categorization.

Further Questions

Many questions concerning the evolution and structure of color categories remain to be answered. Why do red terms seem to be the first hue words to appear in color lexicons? Why do grue categories persist for so long in color-category evolution? How are we to understand the appearance of categories in languages from lands as far apart as New Guinea and North America that lump yellow with green instead of with red?

It is very likely that social factors such as trade and conquest drive the evolution of color vocabularies. It seems clear that culture plays a significant role in both the origins and the boundaries of color categories. Exactly what is that role? Can culture override perceptually based constraints? It appears that a proper understanding of even the denotations – let alone the connotations – of a

language's color terms requires a proper grasp of the relative contributions of biological, cultural, and environmental factors [11].

Bilingual Color Naming/ Categories

Prutha S. Deshpande¹ and Nancy Alvarado²

¹Department of Psychology, Ohio State University, Columbus, OH, USA

²Department of Psychology and Sociology, California State Polytechnic University, Pomona, CA, USA

Definition

A bilingual person is a person fluent in more than one language, either from birth or acquired later in life. A multilingual person is fluent in more than two languages. Color naming is the process of assigning color terms to refer to color appearances in the world. Color categories are mental representations of the regions of color space that are designated by particular color terms or names.

Cross-language Comparisons

The influence of culture on color perception and categorization is most often studied by comparing the use of single-word (monolexic) color terms or Basic Color Terms (see entry ► [“Berlin and Kay Theory”](#)) to name color categories across different languages, as in the **World Color Survey** [1, 2]. Color categorization and naming have been studied across a wide range of cultures to explore questions about the universality of basic

color categories and the ways in which color naming may affect color perception. However, such comparisons between groups of individuals speaking different languages in different cultures necessarily confound differences in individual experience and individual perception with the linguistic properties of the languages spoken, and the categorization practices of the cultures themselves, resulting in a difficulty identifying the distinct contribution of each source of influence on color naming behavior. Comparison of the categorization and naming behavior of multilingual or bilingual individuals using each of their distinct languages provides a way of controlling for individual differences so that the influence of culture and linguistics on naming can be more readily determined.

Cross-language Comparisons Within an Individual

Comparisons of multilingual/bilingual individuals performing identical color naming or categorization tasks separately in each of their languages demonstrate the influence of several factors. The sequence in which languages were acquired and the relative proficiency in each language are important and should be measured in studies of multilingual or bilingual color naming. In some cases, a person may know two or more languages because he or she is an immigrant to a new culture, in the process of acquiring a new language, while using the native language or previously acquired languages less frequently. An individual in the process of assimilating to a new culture and language may experience interference from previous languages. He or she may be motivated to forget, or experience pressure to forget, previously acquired languages, affecting naming behavior. Studies comparing bilingual naming to monolingual naming show increased consensus of response among bilinguals, as well as a preference for use of more basic color terms [3, 4]. The same phenomenon has been observed for emotion terms [5]. In Loitšenko’s [6] comparisons of Estonian/Russian bilinguals dominant in either Estonian or Russian, both groups of bilinguals

showed convergence in their responses in tasks of color listing and naming, with consensus however being higher with the language more frequently used. These patterns perhaps reflect a focus on what is shared across languages, or a vocabulary loss affecting the less frequently used, more differentiated terms needed to describe subtleties of color samples. Others have further suggested that immersion in a new culture may affect the availability of environmental referents, or the communicative salience of specific color differences, and thus the availability of previously learned color terms in semantic memory (see entry ► [“Memory Color”](#)) [7]. For these reasons, bilingual color categorization and naming behavior should be compared to both monolingual immigrant and nonimmigrant populations. Few studies have made such comparisons, even in the literature on bilingualism.

In other cases, a person may be a participant in a multicultural society in which different languages are spoken in different contexts and for different purposes, but are generally spoken frequently enough to be refreshed in memory. Code-switching occurs when bilingual or multilingual individuals spontaneously change languages while speaking. The switching suggests that some concept might be better expressed using a particular language or that access to vocabulary is easier in that language. Study of when and how this occurs is an emerging field in linguistics [8]. In comparisons of bilingual color naming, subjects are required to switch languages to perform the same task twice but are constrained to respond in one language. For example, Deshpande [9] examined the color naming behavior and category extensions of Korean-English bilinguals who repeated the same experimental procedures over two sessions, in each of their language modes. While such comparisons can certainly be informative, it is unclear how much code-switching may be occurring mentally as subjects perform tasks. Further, the requirement to respond in a single language will have an impact on speeded tasks that must be considered in interpretation of results. In studies comparing multilingual/bilingual subjects across languages, the focus is generally not on the factors affecting

voluntary choice of terms, but on how a subject's perceptual choice behavior or categorization and naming of a color sample are affected by use of a specific language. Researchers have asked whether perceptual boundaries match the categories existing within a language and whether perceptual experience changes to fit a second language's categories when a new language is acquired. As yet, no studies have investigated whether an individual might prefer to name colors using the language with the richer color vocabulary, the more differentiated category structure, or perhaps the terms most relevant to performing a particular task.

Color Naming

In general, when bilingual individuals perform color naming tasks in two languages, their behavior suggests a dissociation between cognitive processing based on meaning and language choices dictated by grammar or language structure. Thus, a bilingual person who is assimilating to a new culture can make meaning-based choices based on one culture while using language-related naming behaviors typical of the other culture. For example, Pavlenko and Driagina [10] found that English-speaking bilinguals followed a Russian pattern of intransitive verb use when speaking in Russian but switched to an adjectival pattern in English. In contrast, Jameson and Alvarado [4] found that Vietnamese bilinguals tended to impose both the grammar and category structure of English onto Vietnamese responses when responding in Vietnamese. Thus, bilingual subjects responding in Vietnamese tended to name the category orange (a distinct category in English but not Vietnamese) using the object gloss (the fruit name) in both English and Vietnamese, whereas those monolingual in Vietnamese (in both the United States and Vietnam) named the same color sample using a modified basic term (e.g., *Vàng Dam* or dark yellow, with the adjective following the noun). On the other hand, native Vietnamese speakers responding in English were more likely to use Vietnamese language patterns such as more modified basic terms and compound

terms (e.g., yellow-brown) than native speakers of English, who were more likely to use monolexemes (tan for yellowish-brown colors) and object glosses (bark, baby puke). Thus, bilinguals retained the language structure but not the meaning-based categorization patterns [4, 5]. Alvarado and Jameson [5] found a similar dissociation for emotion terms. It is possible this behavior may be specific to the domain of color terms, since Pavlenko [11] has identified several studies in which a domain of terms (in her case, emotion terms) has been treated differently than other categories of concrete and abstract nouns in a language. This suggests the need for greater caution in use of language-based properties such as concreteness/abstraction as a definition for basic color status and consideration of how the content of a domain might interact with language structure. Within-individual comparisons of naming behavior can help identify such differences in language structure as applied to a specific domain of terms, such as color names.

Color surveys that have emphasized monolexemic naming in a search for single-word basic color terms have disadvantaged those languages employing other strategies for making distinctions between colors, including use of modifiers, suffixes and prefixes to stem terms, intensifiers such as word repetition, and use of multiple-character combinations to name basic colors, such as in Asian languages with nonphonetic writing systems. These interactions of grammar with meaning complicate cross-cultural comparisons used to form theories about basic color naming, but can be clarified by examining behavior of bilingual subjects because meaning-based choices are affected differently than grammar-based choices.

Category Boundaries and Focal Colors

Languages vary in how many color terms they contain and in where they draw category boundaries [1, 2]. Languages in the early stages of **Berlin and Kay's** hierarchy of color category evolution have fewer basic color terms and broader categories with different focal hues. For example, in many Southeast Asian and Asian

languages, it is common to combine the green and blue categories which are distinct in English into a single category (commonly referred to as a “Grue” category). Investigations comparing English speakers with the Tarahumara people of northern Mexico, who also form a broader Grue category [12, 13], suggest that the differences in linguistic distinctions made by the two languages produce differences in decisions about color similarity (see entry on the ► [“Effects of Color Terms on Color Perception and Cognition”](#)). This does not imply that individuals using those languages are unable to recognize differences between green and blue color samples, nor that they cannot perceive distinct hues. As noted above, Asian languages with a Grue category may use a basic color term (such as *Xanh* for Grue in Vietnamese) combined with modifiers to specify the distinct hue (thus *Xanh lá Cây* for leaf green in Vietnamese) of a color sample [3, 4].

In contrast, many languages with more basic color terms than specified by Berlin and Kay's hierarchy have also been described. For example, Russian divides the blue region of color space into two non-overlapping regions, a light/sky blue region and a dark/navy blue region, designated by the basic color terms *goluboj* and *sinij*, respectively [14]. Influences of this category distinction were investigated in visual search tasks by Winawer et al. [15], who found that Russian speakers were able to discriminate two colors faster when they fell into different blue categories in Russian, and this advantage was not shown by English speakers who do not make this category distinction (see entry on ► [“Color Categorical Perception”](#)). Similar distinctions in the blue region of color space are made in Greek [16], Japanese [17], Italian [18], and Ukrainian [19]. Figure 1 provides a sample comparison of color naming by an English-speaking subject [20] and a Japanese-speaking subject [21], differing in the basic color terms used to name blue color samples. Studies have compared monolingual speakers of these languages to bilingual speakers, where in all cases, English was the second language learned. These studies find bilinguals' color categories to be shifted toward those of monolingual speakers of English across a range of tasks,

Bilingual Color Naming/ Categories, Fig. 1

Monolexemic color naming of 330 Munsell color samples, used in the World Color Survey. (a) English-speaking subject #1 [from 20], (b) Japanese-speaking subject #12 [from 21]. As illustrated by these individual subjects, English speakers use one basic color term to name blue color samples, while Japanese speakers use two basic color terms, *mizu* to name light blue color samples and *ao* to name medium to dark blue color samples

including color similarity judgments and visual search (through which categorical effects for color perception have also been demonstrated) [22, 23] and even verbal descriptions of visually more complex stimuli [24]. Paramei et al. [25] however find a shift in the opposite direction, with the majority of their Italian-English bilinguals selecting the foci of English blue to be closer to the foci of Italian *blu* (dark blue). Extralinguistic variables such as second language proficiency, frequency of second language use, and length of stay in second language-speaking country have been suggested to influence category representations of the bilinguals in all of these studies. Additionally, as the last study suggests, linguistic variables such as the phonological and orthographic similarity of color terms in the languages in question (such as with the color terms for English blue and Italian *blu*) may also play a role.

While nearly all of the work discussed above has looked at behavioral evidence for language effects on color, Athanasopoulos et al. [22] find converging neuro-physiological evidence, focusing on an ERP component indicating pre-attentive

differences in the perception of color in monolingual and bilingual speakers (again, see entry ► “Color Categorical Perception”). As has been pursued in other domains of color research (see entries ► “Bayesian Approaches to Color Category Learning” and ► “Color Category Learning in Naming-Game Simulations”), computational models are now being explored to explain behavioral findings in multilingual/bilingual color naming. Matussevych et al. [26], for example, model the shift in bilinguals’ category foci toward the foci of the second learned language, examining the influence of category similarity across languages, and translations for color terms being shared (or not) across languages. As noted by them, their modeling framework could be expanded to more systematically test the influences of the various other linguistic and extralinguistic variables noted previously. Other approaches such as connectionist modeling are also well suited to examining the representation of color categories in the mind of multilingual/bilingual individuals. Zhang et al. [27], for example, present a connectionist model of object

naming, but applications to color naming have not yet been explored.

Color Lexicon Evolution

Since the specification of **Berlin and Kay's Theory** of the evolution of color naming systems, several modifications have been proposed. MacLaury [28] suggests that Berlin and Kay's evolutionary stages reflect a transition from a lightness-based naming system to a hue-based system and that cultures evolve in their naming due to a shift in emphasis from describing similarity to describing difference (see entry on ► ["Vantage Theory of Color"](#)). Schirillo [29] suggests that evolutionary stages may also reflect a transition from use of contextualized names to use of more abstract terms (basic terms are abstract by definition). Van Brakel [30] suggests that stages reflect the influence of Western culture on indigenous naming behaviors and are thus a transition to the Western color system from a variety of viable alternatives (see entry on ► ["Color Dictionaries and Corpora"](#)). However, in studies of unconstrained naming, where subjects are not confined to use of basic color terms, both English speakers and those speaking other languages greatly prefer to describe colors using secondary names or modified basic terms, not basic terms alone. Table 1 provides an example of the variety of basic and non-basic secondary color terms, compound words, and modifiers, used by English and Korean monolinguals, and Korean/English bilinguals, in naming of a color sample (C23 from the World Color Survey palette) [1, 9]. Another example, of British English and Mandarin Chinese color naming, can be found in the work of Lin et al. [31]. If cultures were evolving toward a greater emphasis on describing difference, those cultures with more basic terms should also have more modifiers. The opposite seems to be true – use of modifiers and use of contextualized basic terms seem to vary inversely, suggesting that these are alternative strategies for describing differences in color percepts.

The behavior of multilingual/bilingual speakers may recapitulate this evolutionary process on the individual level to the extent that

immigrants speaking multiple languages are in transition to English from one or more other languages. It can be argued that generalizing from individual language learning to evolution of language stages at the cultural level is justified because (a) the culture's language practices are determined by the behavior of individuals speaking that language; (b) as with individuals, cultures change in part due to contact with other cultures; and (c) the culture's evolutionary stage is measured by assessing the language behaviors of participants sampled from that culture. Otherwise, the processes by which cultures change are not hypothesized to be the same as those by which individuals acquire language abilities. In support of this idea, Jameson and Alvarado [4] found that Vietnamese bilinguals used a basic color term for orange while Vietnamese monolinguals did not and that the focal samples for bilinguals responding in Vietnamese had shifted toward those of monolingual English speakers. However, for these Vietnamese bilinguals, highly specific Vietnamese object glosses and modifiers tended to fall into disuse before basic color terms. Thus, bilingual speakers were unable to fully emulate the pattern of naming used by monolingual English speakers because they did not have access to a large vocabulary of object glosses in Vietnamese (probably due to disuse). More recently, Pavlenko et al. [24] found that Russian monolinguals made much finer distinctions than English monolinguals and bilinguals in describing the color content of paintings such as *The Blue Window* by Matisse and *The Starry Night* by Van Gogh, containing rich variations in shades of blue. As previously noted, Russian has two basic color terms for light and dark blue, while English has one basic color term for the blue region of color space. Just as speakers of Grue languages use modifiers to describe the differences they perceive between green and blue color samples, English speakers can certainly perceive differences in shades of blue and would be able to describe the differences using modifiers such as *Light* and *Sky* or secondary color terms such as *aqua* and *turquoise*, if prompted to do so. However, this behavior may not be observed spontaneously because the distinctions between shades of blue do not hold communicative

Bilingual Color Naming/Categories, Table 1 Unconstrained color naming of a color sample (C23 from the World Color Survey palette) by three language groups:

(1) English monolinguals, (2) Korean/English bilinguals naming in both English and Korean, and (3) Korean monolinguals [9]

English monolinguals (<i>n</i> = 32)		Bilinguals naming in English (<i>n</i> = 34)		Bilinguals naming in Korean (<i>n</i> = 34)		Korean monolinguals (<i>n</i> = 11)

relevance in their language community. The same explanation may hold for the bilingual speakers, who were either from Russian-speaking families but brought up in an English language environment in the United States or were new learners of Russian in the United States. For second language learners of Russian in a Russian language environment, the light/dark blue distinction may be expected to become more salient, as the distinction would be obligatorily made by native Russian speakers. A comparison of multicultural multilingual naming with immigrant multilingual naming is needed to show whether those with richer language experience show an increased tendency to

use their wider vocabularies to describe additional dimensions of perceptual experience.

Alvarado and Jameson [5] suggest that cultures may not evolve from lightness to hue but rather from a single-dimensional naming system (based on lightness) to a multidimensional naming system capturing distinctions related to hue and saturation in addition to lightness. If so, the interaction between dimensions may produce more sharply defined category boundaries than a single dimension alone. In that case, modifier use should increase as cultures attend to additional dimensions. Further, modifiers tend to evolve along with basic terms. As noted, Tarahumara terms like Very and Somewhat evolve to Light

and Bright, terms which are specific to color naming. Vietnamese uses the term Fresh (*Tươi*) to describe saturation, a modifier not used in English but equivalent to terms such as Vivid or Deep. Areas of color space described by lightness modifiers do not vary as much as those described by modifiers capturing other dimensions. This suggests that an evolutionary-stage theory based on a broader spectrum of naming behavior, capturing more aspects of spontaneous naming behavior, might produce a different ordering of stages.

Theoretical Considerations

Comparisons of naming behavior of multilingual individuals across languages provide an approach to testing assumptions of current theories of color naming, such as the assumption that monolexemic naming using basic color terms is a valid approach to comparing languages with widely varying strategies for describing color appearances. For example, as described by Burgess et al. [12], the Tarahumara language used a postposed bound modifier (a modifier added to the end of a stem term) that specifies the relation of the currently named color to the center of the category. This system is different from Chinese, Vietnamese, and English [31], where modifiers are separate words and relational distinctions are subordinated to other distinctions. In contrast, Chinese characters are frequently constructed by compounding several characters into a single character with a new meaning, and all color terms consist of two-character pairs in which the first character specifies the color and the second character specifies that it is a noun referring to the color appearance itself (decontextualized, abstract). When the color name is used as an adjective, the second character is the name of the object taking that color. In Japanese, a different second character is used to differentiate chromatic and achromatic color names [31]. This complicates comparison of the basicness of terms when the focus is on monolexemic naming and on the properties of the language instead of the behavior of the individuals speaking that language. Emphasis on a few basic color categories, in both study and theory, neglects the richness of color naming behavior.

It has been argued that immigrant monolingual speakers in the United States (or elsewhere) are not a suitable population for cross-cultural investigations. When monolingual speakers in immigrant communities do not acquire a new language, there appears to be a close similarity between their responses and those of monolingual speakers in their original country of residence. This may be most true for immigrants living in large insulated neighborhoods in urban areas who can conduct daily business without needing to speak an additional language. In two studies of different domains [4, 8], monolingual Vietnamese speakers in the United States and Saigon produced responses that were closely similar, suggesting that the groups responding in the United States were a close proxy for their counterparts in Vietnam. Cultural contamination cannot be automatically presumed to invalidate every investigation. Although it might also be argued that the availability of Western media may have changed the Vietnamese lexicon, resulting in the close similarity of results among the studies, differences were noted for certain contextualized terms which parallel the differences observed between the American and Vietnamese cultures themselves. For example, differences in categorization and naming of the category orange were observed for bilingual subjects but not for monolingual immigrants living in the United States, who would presumably have been exposed to Western media. Given that such cultural differences were not eliminated by exposure to the media, perhaps everyday social interaction and communication have a greater impact on language than passive media exposure. Findings of the persistence of regional accents in Great Britain in the face of homogenous media speech support this conclusion. To assess this, the level of assimilation should be measured in studies of multilingual/bilingual versus monolingual immigrant speakers.

Study of the cognitive language processing of multilingual/bilingual individuals in color naming tasks has the potential to widen our understanding of how language is used to describe perceptual experience by providing a glimpse into the cognitive processing that can be attributed to meaning distinct from the processing that is related to language, holding individual differences and cultural

differences constant. However, to conduct such studies, comparisons must be broadened to compare bilingual and monolingual subjects in both the native country and the country to which such subjects have emigrated, as well as comparisons between multilingual individuals within multicultural societies in which multiple languages are regularly spoken independent of immigrant experience.

Billmeyer, Fred Wallace, Jr.

Ellen C. Carter

Color Research and Application and, Konica
Minolta, Pennsville, NJ, USA

Fred Wallace Billmeyer, Jr., was an American chemist who contributed through industrial

research and academia to the developing fields of polymer chemistry and color science during the second half of the twentieth century.

Billmeyer was born on August 24, 1919, in Chattanooga, Tennessee. In 1941, he received a B.S. in chemistry from the California Institute of Technology. Then, he received a Ph.D. in physical chemistry from Cornell University in 1945 after studying the measurement of molecular weights by light scattering under Nobel Laureate Peter Debye.

His professional career can be divided into two major parts, focusing first on industry and then on education. Upon graduation from Cornell, he joined the Plastics Department of E. I. du Pont de Nemours and Company, Wilmington, Delaware, where he remained for 20 years. There he worked on various aspects of polymers. Instinctively an educator, he published *Textbook of Polymer Chemistry* (1957) and *Textbook of Polymer Science* (1962), which went through three editions and was also published in Japanese. These books helped to create the academic discipline of polymer science. He served as a visiting professor in chemical engineering at Massachusetts Institute of Technology for the 1960–1961 academic year. Billmeyer increasingly became involved with the growing field of color science. At the University of Delaware, he supervised his first graduate color science student, Joseph Atkins, whose 1964 Ph.D. thesis was on the Absorption and Scattering of Light in Turbid Media.

In 1964, he retired from DuPont to join academia full time as a professor of analytical chemistry at Rensselaer Polytechnic Institute (RPI), Troy, New York. At RPI, he taught and directed research in both polymer and color science and directed the Rensselaer Color Measurement Laboratory until he became professor emeritus in 1984. During his time at RPI, he not only taught and mentored undergraduate and graduate students but also, with Max Saltzman, initiated summer courses about color science for people from industry. His influence on the field of color science was extended throughout the United States by over 1000 people from diverse fields attending these summer programs.

Deepening his commitment to education, he undertook two other major projects while at RPI. In 1966, Professor Billmeyer continued his collaboration with Max Saltzman, publishing *Principles of Color Technology*. Their two editions of this textbook became widely acclaimed throughout the industrial world as the primary introduction to color science. A third edition entitled *Billmeyer and Saltzman's Principles of Color Technology* (published in 2000) by Roy Berns is still widely used. Also with Richard Kelly in 1975, he published *Entering Industry: A Guide for Young Professionals*.

The second project was the creation of an academic journal for color science. After supporting two unsuccessful attempts at journals of color engineering and science, in 1976, he initiated the journal *Color Research and Application*. Billmeyer was the founding editor and served in that position until 1986. His approach of involving national color organizations, beginning with the Canadian Society for Color, the US Inter-Society Color Council, and the Colour Group (Great Britain) and later others throughout the world, has contributed to the success of this English-language journal published by John Wiley & Sons now in its 40th year of continuous publication.

Many of Billmeyer's scientific contributions throughout the years fall into the category of light scattering and the application of turbid medium theory to the formulation and shading of colored materials. Beginning with the basic theory of Beer's law, he programmed a digital computer to calculate the concentrations required to produce a given transparent color by mixing soluble dyes [1]. Next with Beasley and Atkins, he expanded two-flux Kubelka-Munk theory to a four-flux turbid medium theory [2], which became known as the BAB theory for colorant formulation. From there, he continued the development of the BAB to apply particularly to paint systems [3] and expanded that further to coatings with goniometric characteristics [4, 5]. He further developed practices for determining the optical properties needed for use in the turbid medium theory and multi-flux theory [6–9].

Billmeyer was a versatile and prolific communicator; his contributions were not limited to turbid medium theory. Two other areas that should be mentioned here are the characterization of fluorescent materials [10, 11] and use of color difference equations in manufacturing [12]. His involvement within the many professional organizations and collaboration with other scientists throughout the world influenced most areas of color science. In particular, his more than 350 published articles discussed polymer characterization and diverse aspects of color. His 13 books presented in clear, concise language the scientific principles necessary for the industrial use of polymers and color to enhance our lives.

Binocular Color Matching

David R. Simmons
School of Psychology, University of Glasgow,
Glasgow, Scotland, UK

Synonyms

Binocular color perception; Binocular color vision

Definition

In the context of this article, “binocular color matching” refers to color vision with two eyes, focusing on the differences between when two eyes are used to view colors (i.e., binocular or dichoptic color) and when only one is used (i.e., monocular color), as well as phenomena

(largely) unique to binocular vision such as fusion, rivalry, and stereopsis.

Introduction

Most of us have two functioning eyes, and yet we still somehow see the visual world as a single entity, most of the time unaware that our brains are receiving and processing two separate and largely independent sets of visual signals from the outside world. In the context of color vision, this raises some interesting questions:

1. *Binocular color fusion*: How similar do the chromatic properties of visual signals in each eye have to be in order to be perceived as one?
2. *Binocular color rivalry*: How different do the chromatic properties of visual signals in each eye have to be in order to evoke binocular rivalry, which is an alternation in visibility of the visual information going to each eye?
3. *Color and stereopsis*: Stereopsis is the perception of depth that is obtained by analyzing the differences between the images going to each eye. To what extent is this perception of depth affected by the chromatic properties of visual information?
4. *Binocular color summation*: The processing of visual signals is affected by whether or not a scene is viewed with one or two eyes: to what extent do the chromatic properties of visual signals influence this?
5. *Binocular color appearance*: Do colors look different when viewed with one eye or two?

Note that the field of binocular vision and stereopsis has been thoroughly reviewed by Prof. Brian Rogers of the University of Oxford, UK, and Prof. Ian Howard, late of York University, Canada [11], and for all but the most recent studies, the interested reader should refer to them for further information.

Binocular Color Fusion

The problem of binocular fusion, how the world is seen as one despite having two eyes, has fascinated

philosophers and scientists for centuries (see [11] for a historical overview). It makes sense that color might have a role to play in this phenomenon. One might expect a feature in the visual world when viewed with one eye to have the same spectral reflectance properties and therefore presumably appear to be the same color, when viewed with the other eye. Consequently, interocular color similarity would presumably make a good visual cue for fusion. Curiously, however, most of the research effort has gone into investigating what happens when the colors presented to the two eyes are *different*. In particular, there is the controversial issue of *dichoptic color mixture*: when two lights with different chromatic contents are presented separately to each eye, do the lights combine in a similar way to when they are presented superimposed to the same eye or does *binocular rivalry* (an alternation in perception between the stimuli presented to each eye) result (see Fig. 1)? The first investigation of this phenomenon appears to have been in the early eighteenth century using differently colored silks viewed through an aperture [7]. Later, in the nineteenth century, the existence or not of dichoptic color mixture was a further source of controversy between Helmholtz and Hering, given the different predictions of the Young-Helmholtz and Hering theories of color vision. Arguably the most controversial aspect is whether or not “binocular yellow” can be obtained when red light is presented to one eye and green to the other. Recent studies have clarified that true dichoptic color mixture does appear to take place, so long as certain

conditions are met. These are that the mixture is more stable with small and textured patches of light rather than large and homogeneous, with flickering rather than steady stimuli, and with patches of low luminance and saturation which are close in luminance and chromaticity rather than high luminance and saturation with different luminances and chromaticity ([11]; see also [10]). Some of these rules are nicely illustrated in a study by de Weert and Wade [5] (see Fig. 2). In a more recent study, the bold claim is made that “two eyes are worse than one,” based on data suggesting that monocularly visible features of different colors effectively disappear when dichoptically combined [1]. In an earlier study by Simmons [32], however, although detection thresholds for briefly presented iso-luminant red-green gratings in antiphase between the eyes were higher than those for monocular presentation, they were not so high that the signals from each eye were effectively canceling each other out, as suggested by Anstis and Rogers [1]. Potentially, technical issues to do with the accurate registration of stimuli in each eye and the presence

Binocular Color Matching, Fig. 1 Schematic diagram illustrating alternative percepts generated by dichoptic color mixing or binocular rivalry

Binocular Color Matching, Fig. 2 Dichoptic color mixing: fusion of the *upper* two disks gives unstable binocular rivalry; fusion of the *lower* two textured disks produces stable dichoptic color mixing. This illustrates the role of texture in promoting dichoptic color mixing (Taken from de Weert and Wade [5], Reprinted from Vision Research, 28, Charles M.M. de Weert, Nicholas J. Wade, Compound binocular rivalry, 1031–1040, Copyright (1988), with permission from Elsevier)

of barely detectable luminance artifacts complicate the interpretation of these experiments.

A different approach was taken by Malkoc and Kingdom [21], who, following on from an earlier study by Yoonessi and Kingdom [42], measured *dichoptic color difference thresholds (DCDTs)*, which are the thresholds for detecting a color difference between the two eyes, coinciding with the detection of a peculiar phenomenon called *binocular luster*. They found that these thresholds were higher than those for detecting color differences between two stimuli when they were presented side by side, although lower than those required to provoke binocular rivalry (see below). Malkoc and Kingdom [21] also found that these thresholds were best predicted by the perceived color difference between the two stimuli, rather than any considerations based on cardinal or unique hue mechanisms. Kingdom and Libenson [14] specifically investigated the processing of interocular differences in saturation (or color contrast). They found that the appearance of the mixture obtained crucially depended on the relative amounts of luminance and chromatic contrast. With purely chromatic differences between the two eyes (i.e., lights with the same hue but different saturations), the more saturated/higher contrast stimulus dominated the percept, but the presence of a luminance pedestal forced the colors to blend and therefore reduced the saturation of the resultant. Kingdom and Libenson [14] argue from these results that the appearance of a dichoptic color mixture depends on whether or not the brain interprets the information from the two eyes as coming from the same object or not, a phenomenon which they term the “object commonality hypothesis.”

Binocular Color Rivalry

As rivalry is, to a certain extent, the obverse of fusion, most of the issues pertinent to this theme have already been discussed above. It is certainly true that the presentation of saturated red stimuli to one eye and saturated green to the other is often almost paradigmatic in studies where the aim is to evoke binocular rivalry (see, e.g., [2]; also, again,

[5]). O’Shea and Williams [23] demonstrated that S-cone-isolating stimuli could induce binocular rivalry, suggesting that rivalry was not solely confined to luminance or red-green chromatic pathways. A detailed study of the wavelength sensitivity of binocular rivalry was performed by Sagawa [28]. Note that rivalry does not occur for briefly presented stimuli. In these situations the dichoptic stimuli tend to superimpose, although are still distinguishable from monocularly superimposed stimuli [11]. There is some evidence that the chromatic system is more affected by binocular rivalry suppression than the achromatic system [11, 24]. Mullen et al. [22] found that the visibility of chromatic grating stimuli presented to one eye was affected by the presence of luminance stimuli in the other, suggesting that, when stimuli differ between the two eyes, the suppression of one eye by the other is independent of whether the stimulus contains color or luminance contrast (which is not the case for monocular vision, or when the stimulus is the same in both eyes, when the suppression of one stimulus by another, masking, stimulus is more selective).

Color and Stereopsis

There are two issues which have dominated research on color and stereopsis. The first is whether or not there is actually a functioning chromatic stereopsis mechanism. The second is whether or not chromatic information helps to solve the stereo correspondence problem. In both cases the arguments have been similar to those in color motion perception. Historically, a good way of testing whether or not a purely chromatic mechanism exists has been to test performance at *isoluminance*, when the visual patterns in question are theoretically defined solely by chromatic contrast, without any luminance contrast being present. The earliest study of stereopsis at isoluminance suggested that stereoscopic depth perception was very weak and possibly nonexistent at red-green isoluminance [20]. Subsequent studies provided conflicting results, depending on the precise stimulus characteristics [11]. Around the early 1990s, the extreme views on this issue

were represented by two studies: Livingstone and Hubel [19] and Scharff and Geisler [29]. Livingstone and Hubel [19] claimed that all previous demonstrations of intact stereoscopic depth perception were artifactual, and down to the technical difficulties associated with removing all luminance information from the stimulus. Their view that stereopsis was essentially “color blind” was consistent with their theories on the parallel processing of visual information by magnocellular- and parvocellular-mediated visual pathways, with stereopsis mediated by the “color-blind” magnocellular stream. Scharff and Geisler [29], on the other hand, claimed that their careful calibration of the stimulus, accounting for all potential luminance artifacts, not only demonstrated that stereopsis was possible at isoluminance but that it was as good as it could be, given the limits on obtainable color contrast due to the overlap in spectral sensitivities of long- and medium-wavelength-sensitive cones. In a series of studies published between 1994 and 2002, Simmons and Kingdom updated this view of the status of stereopsis at isoluminance to demonstrate that there exists a rudimentary chromatic stereopsis mechanism which is less contrast sensitive and has a more limited disparity range, poorer stereoacuity, and poorer ability to encode a stereoscopically

defined shape than its luminance counterpart ([15, 17, 33–35]; reviewed in [16]). While this view was challenged in a study by Krauskopf and Forte [43], who argued, similarly to Livingstone and Hubel [19], for a complete disappearance of stereopsis at isoluminance, their data could be partially explained by the presence of high spatial frequency luminance artifacts in their stimuli. Having said that, it is very difficult to control for these artifacts, especially given the high contrast sensitivity of luminance-based stereopsis [31, 37]. While most of the above studies were carried out at red-green isoluminance, Grinberg and Williams [9] demonstrated that stereopsis is also possible at “blue-yellow” isoluminance.

Can chromatic information help to solve the stereo correspondence problem? The correspondence problem in stereopsis refers to the ability of the human brain to work out which feature in one eye’s view matches with which feature in the other eye’s view (see Fig. 3). As stated above, it makes sense that chromatic information could help in solving this problem, and, sure enough, a number of studies have demonstrated that this is indeed the case (e.g., [6, 12, 18]). Simmons and Kingdom [36] argued that these results might be explicable in terms of the interactions between different

Binocular Color Matching, Fig. 3 Schematic illustration of the potential role of color in the stereo correspondence problem. If the images illustrated are presented to the left and right eyes, respectively, if color promotes stereo correspondence, then a *green bar* will appear in front and a

red bar behind the fixation plane (*upper right*). If color has no role, then four bars will be seen in the frontoparallel plane (*lower right*). The bars colored *yellow* might also appear rivalrous, depending on the precise stimulus conditions

independent stereopsis mechanisms, some of which are sensitive to chromatic contrast (see also [38]). Wardle and Gillam [41] have argued that color information is also important in the so-called da Vinci stereopsis, which is the perception of depth obtained, under certain viewing conditions, from visual regions only visible to one eye.

There are some complicated dependences of stereoscopic sensitivity on stimulus dynamics at isoluminance which were investigated by Tyler and Cavanagh [39]. Note that the phenomenon of *chromostereopsis*, most often experienced as a saturated red target appearing in front of a saturated blue one (when viewed with two eyes) despite the stimuli being physically in the same depth plane, is thought to be largely due to chromatic aberrations in the eye inducing a relative difference (i.e., disparity) in the retinal locations of the red and blue objects in each eye [11, 25]. Figure 4, especially if presented on a data projector and viewed in a dark room, normally induces a strong sensation of this illusory depth percept.

Binocular Color Summation

To what extent does viewing a chromatic stimulus with two eyes affect its visibility or the performance obtained with it? The scientific literature presents a somewhat confusing picture, with Anstis and Rogers [1] claiming that “two eyes are worse than one,” Tyler and Cavanagh [39] claiming that “two eyes” are “as sensitive as one,” and Simmons [32] finding evidence for

binocular contrast summation close to “full summation,” when contrast is effectively linearly added between the eyes, and so a binocular stimulus is twice as detectable as when presented to both eyes rather than one (this would be “two eyes are twice as good as one”!). The conditions under which dichoptic color mixing is obtained have already been outlined above. It therefore suffices to say that the extent of binocular summation for a given chromatic stimulus will depend on the task and the precise chromatic and spatiotemporal parameters of the stimulus.

Binocular Color Appearance

Those of us who have typical binocular vision will have a region of binocular overlap in the middle of the visual field flanked on either side by regions that are only visible in one or the other eye. However, we are usually not aware that colors change in the center versus the periphery of our visual field, although changes are detectable under controlled laboratory conditions [3, 26]. A whole range of dichoptic mechanisms have been proposed to account for these apparent compensations between the two eyes. Shimono et al. [30] suggested a model which takes into account previous results on interocular transfer of chromatic adaptation and chromatic induction effects (e.g., [4, 8, 40]) by proposing a “purely binocular” chromatic mechanism, which responds only to simultaneous binocular presentation of similar colors to each eye but which also inhibits the responses of “purely monocular” color mechanisms (see Fig. 5). This model would also seem to be reasonable in the light of physiological data collected from monkey visual cortex [27]. However, more recent results, such as those of Kingdom and Libenson [14] and Mullen et al. [22] (discussed above), complicate this simple picture.

Another aspect of binocular color appearance that has recently received attention is how presenting different colors to the two eyes can be an easy way to simulate surface glossiness in stereoscopic visual displays, without the need to create a detailed reflectance model [13].

Binocular Color Matching, Fig. 4 Stimulus for chromostereopsis. If viewed on the full screen (especially if presented on a data projector), most people will see the red “CHROMO” look slightly in front of the blue “STEREOPSIS”

Binocular Color Matching, Fig. 5 Model from Shimono et al. [30] which illustrates the inhibitory action of their proposed “purely chromatic” binocular mechanism on monocular mechanisms (Taken from Shimono et al. [30], Reprinted from Vision Research, 49, Shimono, K., Shioiri, S., Yaguchi, H., Psychophysical evidence for a purely binocular color system, 202–210, Copyright (2009), with permission from Elsevier)

Conclusion

The field of binocular color vision has proven surprisingly controversial over the years, with the existence of true dichoptic color mixing, the contribution of color to stereopsis, and the presence or not of a purely binocular color mechanism being key battlegrounds. The current consensus of the field appears to be that dichoptic color mixing can happen, that chromatic mechanisms contribute to stereopsis, and that there is a purely binocular color mechanism, but demonstrating these things requires careful stimulus control and experimental technique. Added to this there are some curious phenomena such as being able to make stimuli which are easily detectable when viewed monocularly disappear when viewed binocularly [1] and the interocular transfer of chromatic induction [8] (Fig. 6). It seems that we still have some more work to do before we can say that we fully understand the complex interactions between binocular color mechanisms.

Binocular Color Matching, Fig. 6 Binocular color induction in monocular patches. Sets of multicolored stereograms are shown for three different color combinations. (a) The *white*, monocular patches gradually fill with distinct pastel colors during binocular viewing of the stereograms. The buildup of the effect typically takes a few seconds. Dependent on the viewer, the full development of the colors may even take minutes. The color effects are most compelling when the stereograms are viewed printed out and in bright light (see original publication). When one eye is closed, the illusion gradually becomes weaker and disappears. This buildup and decay of the illusion after opening or closing one eye indicates that the color appearances are induced by a binocular mechanism. (b) During binocular viewing, the *white*, binocular patches do not change color. During monocular viewing after a period of binocular viewing, however, induced colors are apparent in the patches (Taken from Erkelens and Van Ee [8], Reprinted from Vision Research, 42, Erkelens, C.J., Van Ee, R., Multi-coloured stereograms unveil two binocular colour mechanisms in human vision, 1103–1112, Copyright (2002), with permission from Elsevier)

Blackbody locus – [Planckian locus](#)

Definition

A *blackbody* is an ideal thermal radiator that absorbs completely all incident radiation whatever the wavelength, the direction of incidence, or the polarization [1]. This radiator has, for any wavelength and any direction, the maximum spectral concentration of radiance for a thermal radiator in thermal equilibrium at a given temperature.

Blackbody radiation is radiant energy emitted by an ideal black surface (blackbody) whose spectral power distribution is only governed by its own temperature.

Blackbody color is the temperature of a true blackbody emitter which to the human eye is a close match to the color of an incandescent object, which is not a blackbody.

Blackbody locus is the locus of points in a chromaticity diagram that represents chromaticities of the radiation of Planckian radiators at different temperatures.

Description

All bodies at nonzero temperature absorb and emit radiation. If a body is at thermal equilibrium, it is because the amount of radiation that is emitted per second is equal to the amount absorbed. A blackbody (or ideal Planckian or black radiator) is a body that can completely absorb radiation at any wavelength and completely emit radiation at any wavelength so that it emits more radiant power at each wavelength than any other object at the same temperature. A blackbody is not only an ideal emitter but also a diffuse emitter, which means that the emitted radiation is isotropic or independent of direction [2]. It gets its name because of the fact that, at room temperature, it appears visibly black.

In the late nineteenth century, Kirchhoff [3] and other experimental physicists found that an ideal blackbody, in thermodynamic equilibrium, emitted radiant energy whose spectrum was continuous and a function only of its wavelength and temperature, independent of the nature of the blackbody. However, this behavior could not be explained using thermodynamics or classical

statistical mechanics. It was not until Einstein introduced the idea that light could be quantized that Planck formulated his blackbody radiation law based upon this principle [4]. This is generally known as *Planck's law* and gives the amount of power emitted by a blackbody in equilibrium at a temperature T according to:

$$M_e(\lambda, T) = \frac{c_1}{\lambda^5} \left(\frac{1}{e^{c_2/\lambda T} - 1} \right)$$

where $M_e(\lambda, T)$ is the spectral radiant exitance (power per unit area per unit wavelength interval), λ is the wavelength in meters, and T is the absolute temperature in kelvins. The constants c_1 and c_2 are known as Planck's radiation constants and have the values: $c_1 = 2\pi hc^2 = 3.74177 \times 10^{-16} \text{ W m}^2$; $c_2 = hc/k = 1.43878 \times 10^{-2} \text{ m K}$, where h is Planck's constant, c is the speed of light in vacuum, and k is Boltzmann's constant.

The spectral power distributions of some blackbody radiators at different temperatures are shown in Fig. 1. It can be seen that the peak of the blackbody radiation curve shifts to shorter wavelength and higher energy with increasing

Blackbody and Blackbody Radiation, Fig. 1 Blackbody spectral exitance curves for several temperatures

temperature. At room temperature (300 K), the peak of the curve is at about 10 μm , and the emission is largely thermal in the infrared region. As discussed above, this room-temperature blackbody that has essentially no emission in the visible region appears black. However, as the temperature of the blackbody source rises through the range shown, it increasingly emits in the visible region, and its color changes continuously from black to red through orange and yellow to white and finally a bluish white.

The color coordinates of these blackbody sources at different temperatures can be plotted on a chromaticity diagram. This is shown in Fig. 2, which shows that as the temperature of the blackbody radiator increases, its CIE chromaticity coordinates (x, y) move along a curved line in the CIE 1931 chromaticity diagram. This curve is known as the *blackbody* or *Planckian locus*. For white light sources for general lighting applications, they are designed so that their CIE chromaticities (u^*v^*) are located near this Planckian locus, when plotted on a Uniform Color Scale (UCS) diagram (u^*v^*).

For colorimetric applications, the International Commission on Illumination (CIE) has defined a standard illuminant A, which is representative of illumination under incandescent lighting [5] and whose values of relative spectral power distribution are that of a Planckian radiator at a temperature of approximately 2856 K. It is important to note that while the original CIE standard illuminant A was defined in 1931 in terms of a relative spectral power distribution of a Planckian radiator at a temperature of 2848 K, the Planckian radiation constants, c_1 and c_2 , have changed several times since then (in 1948, 1968, and 1990) with changes in the International Temperature Scale (ITS), causing a corresponding change in the associated temperature. For this reason, the CIE Standard which currently defines CIE standard illuminant A is no longer a function of temperature [5]. However, for an artificial source that is representative of CIE standard illuminant A, the concept of *correlated color temperature* is used, which is the temperature of the Planckian radiator having a chromaticity along the Planckian locus nearest the chromaticity calculated for the spectral

Blackbody and Blackbody Radiation,

Fig. 2 CIE 1931 chromaticity diagram showing the locus of blackbody radiators calculated for Planckian temperatures from 1500 K to infinity; the Planckian temperature that provides the smallest chromaticity difference between an artificial source and this blackbody locus is its correlated color temperature, T_c

distribution of the test source. There are also many artificial white light sources whose spectral power distribution is very different from a blackbody source, such as fluorescent lamps and sources based on light-emitting diodes. However, the concept of correlated color temperature is still used to describe the colorimetric properties of these types of white light sources.

For astronomical applications, the electromagnetic radiation from stars and planets is sometimes characterized in terms of an *effective temperature*, the temperature of a blackbody that would emit the same total flux of electromagnetic energy. However, stars are observed at a depth inside the atmosphere (the photosphere), so it is more typical to describe a star's visual surface by its *photospheric temperature* (see entry on ► [“Apparent Magnitude, Astronomy”](#)).

There are several other important properties of blackbody sources that are given by the following three laws [6]:

Stefan-Boltzmann Law: This law states that the total radiant exitance, M of a blackbody, determined by integrating the spectral radiant exitance curve, $M_e(\lambda)$, for all wavelengths, λ , is proportional to the fourth power of its absolute temperature:

$$M = \sigma T^4$$

where σ is Stefan's constant ($=0.567037 \times 10^{-7} \text{ Wm}^2 \text{ K}^{-4}$). No surface at thermal equilibrium can emit more than this amount of energy.

Kirchhoff's Law of Thermal Radiation: This law states that, at each wavelength, the emissivity of the blackbody, $\varepsilon(\lambda)$, at thermal equilibrium is equal to its absorptivity, $\alpha(\lambda)$:

$$\varepsilon(\lambda) = \alpha(\lambda)$$

Wien's Displacement Law: This law states that the curves of the spectral power distribution of the blackbody radiation are peaked at a wavelength, λ_{peak} , given by:

$$\lambda_{\text{peak}} = \frac{2898}{T}$$

This can be simply shown by differentiating the Planckian spectral power distribution with respect to wavelength and solving the derivative when it equals zero.

Examples

Since the last century, blackbody radiation has been of great interest for use as a primary (calculable) source because the properties are universal and independent of the particular material substance. A good laboratory implementation of a blackbody is a small hole in the wall of an otherwise opaque cavity [7]. The light that enters the cavity through the hole will undergo so many reflections before it can escape from the hole that the light will be effectively absorbed and the hole will appear black. Until 1979, a blackbody like this, heated to the temperature of melting platinum, was the basis of the definition and realization of the SI base unit for photometry, the candela [8].

The earliest types of artificial light were based on heating an object until it was red hot or hotter and was able to emit visible light. These types of artificial light sources are referred to as *incandescent*. Examples of incandescent objects are fire, candles, carbon arcs, and tungsten-filament lamps. They emit radiation with approximately the same spectral power distribution as a blackbody but with an intensity reduced by a factor called the *emissivity*, ε . If the emissivity does not vary with wavelength, the source is called a *gray body* or *nonselective radiator*. An incandescent tungsten-filament lamp is close to being a gray body with an emissivity of approximately 0.40 [7]. The temperature of a blackbody that is closest in color to this gray body source is often used as an index of its color. This is referred to as the *correlated color temperature*, T_c . An alternative index is the *distribution temperature*, which is the temperature of a blackbody whose relative spectral power distribution is closest to that of the source in question. However, all three terms should be

used with caution as they do not give a full picture of the actual spectral distribution [9]. Typical tungsten-filament lamps have correlated color temperatures and distribution temperatures in the range of 2500–3000 K.

However, these incandescent lamps emit not only visible light but a significant amount of infrared radiation which makes them inefficient as light sources compared with more modern lighting technologies, such as solid-state lighting which can be designed to emit optical radiation only in the visible range.

There are many examples of everyday materials that behave like blackbodies but emit significant thermal radiation. The human body is one example of a blackbody radiator which emits at roughly 300 K. Another obvious example is the Sun, whose surface is roughly 6000 K. The Earth is also considered to be a blackbody radiator, but it is less than ideal.

Definition

Radiators that emit UV-A radiation together with very little visible radiation.

Ultraviolet Radiators and Blacklight Lamps

Many different ultraviolet radiators, based on both gas discharge lamp and light-emitting diode technologies, are produced for industrial applications such as photochemical processes, drying and hardening of materials, lithography, and reprography; for disinfection purposes and insect repellents; and for phototherapy and sun tanning. These radiators are available in types that radiate in the UV-A (wavelength range, 315–400 nm),

Blacklight Lamp,

Fig. 1 Blacklight show: different fluorescent dyes used in the clothing material light up in different colors under UV-A blacklight lamps (Photograph: Blacklight Theatre Prague: Creative Commons Attribution-ShareLike 4.0 International)

UV-B (280–315 nm), and UV-C (100–280 nm) part of the spectrum. In the applications listed above, visual effects play no role. Another type of ultraviolet radiators is produced to make fluorescent substances in materials visible to the eye. These radiators produce for this purpose UV-A radiation combined with a very small part of visible radiation, which are mainly dealt with here. They are usually called blacklight lamps. Blacklight lamps are used for artistic and decorative reasons (especially in theaters, discos, and bars; Fig. 1) and for making fluorescent dyes visible in banknotes, stamps, and documents to detect counterfeits, for forensic crime scene inspections, and for making fluorescent bacterial infections visible for medical purposes. Some artists have specialized themselves in using fluorescent paints. Their paintings are meant to be seen under blacklight lamps (Fig. 2).

Working Principle and Properties of Blacklight Lamps

Three different types of light sources are used to produce blacklight lamps:

- Low-pressure mercury lamps (both in tubular and compact shape).

- High-pressure mercury lamps.
- Light-emitting diodes (LEDs).

For the mercury-based blacklight radiators, the only difference compared with the mercury lamp executions that produce mainly visible light is the type of glass and the type of fluorescent powder used. As discussed in the relevant lamp chapters (low-pressure mercury lamps and high-pressure mercury lamps), these lamps produce ultraviolet radiation as a result of the discharge between two electrodes. The glass of the discharge tube of the blacklight versions is produced either of Wood's glass that transmits ultraviolet and infrared radiation but blocks most visible radiation (with the exception of violet around 400 nm and deep red around 800 nm) or of regular glass coated with a filter that transmits ultraviolet and blocks most of the visible radiation. Wood's lamps were introduced in the First World War as invisible signal beams used for communication [1]. The coated regular glass lamps emit UV-A radiation together with violet-bluish visible light. Their spectrum depends on the type of fluorescent powder used on the interior of the discharge tube. Either barium disilicate (industrial designation "BSP") with a resulting peak wavelength at 349 nm or strontium tetraborate (industrial designation "SBE") with a peak wavelength at 368 nm is used. The high-

Blacklight Lamp,

Fig. 2 Paintings by the artist Beo Beyond produced with fluorescent paint displayed in the artist's own blacklight studio in Barcelona, Spain (Photograph: Beo Beyond: Creative Commons Attribution-Share-Alike 3.0 Unported)

pressure mercury type of blacklight lamp exists in fluorescent-coated (SBE) and clear versions. The fluorescent version has a higher radiant flux in UV-A, while the clear version has a more concentrated light-emitting area making it more suitable for use in reflector type of luminaires. The high-pressure mercury blacklight lamps are more compact than the low-pressure mercury lamps when comparing the same ultraviolet radiation output. They can, therefore, be used in floodlight type of luminaires as used for theatrical and concert performances. They are also available in higher output versions. The low-pressure mercury versions are available in the wattage range from 4 to 36 W with UV-A radiation output power between some 1 and 10 W. The high-pressure versions are available in the wattage range from 100 to 1000 W with UV-A radiation output between some 50 and 500 W.

Blacklight LEDs that emit radiation around the 390–420 nm wavelength range are increasingly replacing the mercury-based blacklight lamps. The semiconductor material used for UV-A LEDs is gallium nitride (GaN) or aluminum gallium nitride (AlGaN). UV-LEDs emit the UV radiation directly without the use of phosphors

or filters. They have a small spectrum (quasi-monochromatic). Blacklight LEDs are available in a wide range of wattages, lumen packages, and intensities. They are produced in spotlight as well as strip or string versions and in many different dimensions. The string versions are used to combine the fluorescent effect on radiated materials in a space with the decorating effect of the purple glowing string, which can be shaped in all kind of forms.

Safety

Blacklight lamps radiate part of their light in the upper range of the UV-A spectrum which borders onto the visible part of the spectrum. The UV-A part of the total range of UV radiation (UV-C, UV-B, and UV-A) is the least hazardous part of the ultraviolet spectrum. Hazardous here relates to the risk of damage of the human skin and product materials. Radiation with wavelengths nearest to the visible part of the spectrum is, in turn, the least hazardous part of the total UV-A range. It is the combination of radiation power installed, the wavelengths that the actual blacklights radiate,

and the time of radiation exposure that determines possible hazards. For situations where the blacklight source is in the direct line of sight, also the radiance (the radiation equivalent for luminance) plays an essential role. Many blacklight installations are safe, if care is taken that the blacklight sources are outside the direct lines of sight. But, the first three aspects listed above vary from installation to installation so that it is wise to check if safety limits are not exceeded. Especially evaluating the exposure time for the working staff, who may be exposed for periods of around 8 hours, may be necessary in this context.

Blind Spot

Jonathan Aboshiha
The UCL Institute of Ophthalmology and
Moorfields Eye Hospital, London, UK

Synonyms

[Physiologic scotoma](#); [Punctum cecum](#)

Definition

Blind spot is the name given to the scotomatous area of each eye's visual field that lacks visual input, due to the photoreceptor-free region of the retina where the optic nerve exits the eye.

Overview

The phenomenon of the blind spot was first described in 1668 by the French Roman Catholic priest and scientist Edme Mariotte, who used small circles of white paper to locate the region of visual space in which they disappeared [1]. Prior to this discovery, the role of the optic disc was not clear, and scientists such as Leonardo da Vinci (1452–1519) had thought that the visual image actually fell only on the head of the optic nerve itself [2]. The vertically oval area of the blind spot subtends about $5 \times 7^\circ$ of visual angle and corresponds to the projection in visual space of the optic nerve head, which has average vertical and horizontal disc diameters of 1.88 and 1.77 mm, respectively [3]. The physiological blind spot is centered about 15° temporally from the point of fixation, due to the nasal anatomical location of the optic nerve head in relation to the

Blind Spot, Fig. 1

fovea (Fig. 1). One is normally not aware of the area of the visual field which corresponds to the blind spot in binocular vision, due to the fellow eye's retinal and cortical representation of the corresponding area of the visual field. Even in monocular vision, this region is perceptually filled in at a cortical level using the brightness, color, and texture detected in the visual field adjacent to the blind spot [4]. This filling in of the scotomatous area of visual field caused by the optic nerve head has also been shown to be an active process involving spatial integration, wherein the pattern and color of not just the area immediately adjacent to the scotoma but also from the more remote surround are used to perceptually fill in the scotomatous region [5].

The size of the blind spot strongly correlates with the area of the optic disc, as well as other features such as the region around the nerve head where the retina has wasted away (i.e., parapapillary chorioretinal atrophy) [6] and the surface topography of the disc, with the more prominent nasal part of the disc appearing less "blind" than the shallow temporal part, probably due to a higher degree of light scattering by the more prominent nasal disc region [7]. In certain pathological conditions, most of which affect the optic nerve head, such as inflammation (i.e., optic neuritis) or optic disc swelling due to raised intracranial pressure, the area of the blind spot can become enlarged, and this can be detected clinically using automated visual field tests or, in more gross abnormalities, confrontational estimation of the blind spot size using a small target such as red hatpin in direct comparison with a normal observer's blind spot. Such pathological conditions of the optic nerve are often associated with defects in color vision, most classically that of red desaturation. These defects may be further evident on testing using pseudo isochromatic plates, typically demonstrating more severe red-green deficits with milder blue-yellow losses [8]. Only the vertebrate eye has a physiological blind spot, on account of light having to pass through the anterior retinal nerve fiber layer (which forms the optic nerve head as it exits the

eye) in order to reach the photoreceptor layer beneath; cephalopods, such as the squid and octopus, have retinæ wherein the nerve fiber layer lies behind the photoreceptor layer and so have no physiological blind spot [9].

Carbon Arc Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Synonyms

[Arc lamps](#)

Definition

Lamps consisting of two rods of carbon in the open air or in a glass enclosure. The ends of the rods touch each other and are connected to a current source. By subsequently separating the rods, a discharge arc is produced that brings the ends of the rods to bright incandescence.

Carbon Arc Electric Lamps

In contrast to what many people think, it is not the incandescent lamp, but the carbon arc lamp that was the first electric light source used.

Already in 1810, Humphry Davy demonstrated in the Royal Institution in London a bright arc between two pieces of charcoal connected to 2,000 voltaic cells [1–3]. Electric carbon arc lighting really took off after the introduction of steam-driven generators around 1850, some 30 years before the introduction of the incandescent lamp. The earliest practical application of electric light was an arc lamp used to simulate the sun in the opera of Paris in 1849 [1]. Arc lamps with their concentrated light of high intensity were, in their infancy, especially used for beacon and searchlights. From 1870 onwards, arc lamps became popular for the lighting of streets, factory halls, railway stations, and big department stores. Huge structures, sometimes called moonlight towers, were used in cities to illuminate large areas instead of using many small masts with gas lanterns. The arc lamp had such a high intensity that it was seldom used in domestic lighting.

From the beginning of the twentieth century, incandescent electric lighting quickly replaced carbon arc lighting installations. Up to the 1950s, extremely high-intensity arc lamps were still used in searchlights, in film studios, and in cinema projectors, until the short-arc gas discharge xenon lamp took over. Today, electrical arcs are used not for lighting but for industrial purposes, as, for example, in plasma torches and welding apparatus where an arc is created between the one welding rod and the metal material to be welded.

Working Principle

When two pointed carbon rods connected to an electric current source touch each other, the resistance at the pointed ends is so high that the rods are heated and begin to glow. When subsequently the rods are separated, they are warm enough for the negatively charged one to easily emit electrons: a discharge is created between the two rods. Usually, the carbon rods are referred to as electrodes; the negative charged one, the cathode, and the positively charged one, the anode. The electrons of the discharge move from the negative to the positive carbon electrode and bombard the anode, heating it. The largest part of the bright light does not come from the arc discharge itself but from the end of the electrodes which are brought to incandescence. The heated air around the discharge rises and makes the bright area rise in the form of an arch giving the lamp its name of arc lamp (Fig. 1).

The gap between the rods is just a few millimeters, and the light-emitting area, therefore, is so small that concentrated light of high intensity is created. The carbon rods burn away with time; in a DC supply, the positive rod burns more quickly than the negative rod because it becomes hotter. The distance between the rods has to be adapted regularly as the arc will extinguish if the distance

becomes too large. Many different mechanisms have been invented to perform this automatically. After some time, the rods become so short that they have to be replaced.

An arc lamp has a negative-resistance characteristic (like all gas discharge lamps) and needs, therefore, a resistor, usually an inductive coil, in its electric circuit to limit the current.

Materials and Construction

Electrodes

Common Carbon Rods

Charcoal was initially used for the electrodes, but charcoal burns away rapidly. It was soon discovered that rods made out of carbon have a much longer life. Hard molded carbon rods were therefore used which later got a core of soft carbon. DC-operated lamps used for the anode a thicker carbon rod than for the cathode to make them burning away with the same rate. In AC-operated lamps, the burning rate of some 20 mm per hour of anode and cathode is, of course, the same [1, 3]. The rods have a diameter of 10 mm to slightly more than 15 mm and were made as long as possible, up to some 500 mm, giving a lifetime of up to 24 h.

Jablochkoff's Parallel Electrodes

Around 1880, the Russ Paul Jablochkoff introduced a whole new concept of electrodes that did away with the need for continuous regulation of the distance between the rods. The "Jablochkoff electric candle," as it is usually called, consists of two parallel rods of carbon separated by plaster (Fig. 2). For ignition, a bridge piece of carbon is positioned at the top. The plaster functions as an electric isolator between the rods and restricts the arc to the top of the electrodes. The plaster crumbles off as the carbon burns down. The position of the light-emitting area moves down with the burning of the candle, making these devices unsuitable for projection type of applications. Since the candle was burned up in 1–2 h, automatic replacement mechanisms for the candles were introduced.

Carbon Arc Lamp, Fig. 1 Because of the rise of heated air, the arc rises in the form of an arch. (Photograph: Achgro: Creative Commons 3.0 unported)

Carbon Arc Lamp, Fig. 2 Jablochkoff parallel carbon electrodes, separate and as used in an enclosed lantern (Drawing 1876) [6]

Carbon Rods with Additives (Flame Arc Lamps)

Just before 1900, fluorides of certain metals (including rare earth metals) were added to the carbon rods. When the electrodes become hot, the metallic salts evaporate and take part in the arc discharge, enveloping the arc as a flame, hence the name of flame arc. Both the lumen output and the luminous efficacy increase considerably with a factor between 2 and 4. These types are therefore also referred to as “high-intensity arc lamps.” Rare earth additives emit a line spectrum resulting in bright white light. Other types of additives emit different colors of light as, for example, calcium, emitting explicitly yellow light, and strontium, red light. In this way, light sources emitting specific spectra suitable for chemical and photographic processes were produced [3].

Electrodes Regulator

As has been mentioned, the distance between the rods has to be adapted regularly as the arc will

Carbon Arc Lamp, Fig. 3 The principle of a self-regulating mechanism making use of the force of a spring (blue) and that of an electromagnet (red)

extinguish if the distance becomes too large in the process of burning off material from the rods. Simple hand-regulated devices were designed where, by turning one screw, both electrodes were adjusted so that the light-emitting area remained at the same location. These systems have long been used in arc lamps for cinema projection.

Early self-regulating mechanisms made use of a clockwork winding device. Later mechanisms use the force of electromagnets. The force of an electromagnet, put in the same circuit as the rods, pushes the rods apart (Fig. 3). At the same moment, the rods are pulled together by gravity force or, as in Fig. 3, by spring force. When the gap between the rods increases, the resistance in the circuit increases and the current therefore decreases. Because of the decreased current, the pushing force of the electromagnet decreases as well, so that the gap size and gap position remain unchanged. The same mechanism takes care of automatic ignition when the power is turned on. When the power is switched off, the rods move to each other until they touch because of the spring force. When the power is switched on again, the large current through the system and thus through the electromagnet moves the rods from each other against the spring force, igniting the lamp automatically. For accurate control,

Carbon Arc Lamp, Fig. 4 A self-regulating arc lamp, after Foucault, balancing the force of gravity with the force of an electromagnet [1]

sometimes complicated clockwork types of gears were applied (Fig. 4).

Lantern

Enclosed Arc

Around 1900, the enclosed arc was introduced with which the lifetime of the carbon rods was increased with a factor of more than five. In a glass globe surrounding the arc, the oxygen is rapidly consumed by the burning electrodes and thereafter the carbon is burned away much slower. Burning times of up to 150 h are possible without rod replacement [1, 3]. Both the light output and the efficacy of the enclosed arc lamp are slightly

lower than that of the open arc lamp. Figure 5 shows a page of a catalogue with some enclosed carbon arc street-lighting lanterns from the early last century.

Optics

For low-mast street-lighting applications and for indoor industrial applications, lanterns usually employed opal or prismatic glass covers. The compact high-intensity light of arc lamps makes them preeminently suitable for floodlighting, for signal lights (in lighthouses, for example), and for searchlights. For this purpose, advanced mirror optical systems were designed (Fig. 6).

Properties

Open carbon arc lamps have a light output of up to some 4,000 lm (500 W versions) at a luminous efficacy of some 4–8 lm/W. Enclosed lamps have a 10–15% lower output and efficacy. Flame arc lamps, using carbon rods with additives, have a light output up to 15,000 lm (500 W versions) at efficacies between 15 and 30 lm/W [3]. Some arc lamps designed for use in searchlights have wattages of more than 20 kW. Beam intensities of up to 5,000 million candelas have been reported with mirror diameters of more than 2 m.

Arc lamps are often not rated by power but by the current they draw. Lamps with currents from 5 to 1,000 amp have been produced.

The correlated color temperature of some 3800 K of arc lamps [5] is much higher than what one was accustomed to with oil, candle, and gas lighting. The high-intensity flame arc lamps have relatively high color temperatures, depending on the material, up to 5,000 K. The spectrum of flame arc lamps extends well into the ultraviolet part (UV-A, B, and C) so that care is required with open arc lamps. Special arc lamp devices for tanning purposes have in fact been produced.

Arc lamps produce a buzzing sound which in interiors was experienced as annoying.

Chevreul, Michel-Eugène

Georges Roque
Centre National de la Recherche Scientifique
(CNRS), Paris, France

Definition

Michel-Eugène Chevreul (1786–1889) is one of the most important chemists of nineteenth-century France. A pioneer of organic chemistry, he was

twice President of the French Academy of Sciences. His work changed dramatically after his appointment as director of the dyeing department of the Gobelins Manufacture in Paris, where he worked for almost 60 years. At the Gobelins, he developed a considerable amount of work on color, including color classification, color applied to industry, as well as his most famous book on simultaneous contrast of colors, which had a great impact on several generations of artists as well as on color teaching. His exceptional longevity helped him to publish many books and hundreds of scientific papers, most of them on color topics. His 100th birthday was celebrated as a national event; he finally died at 103. His book *The Principles of Harmony and Contrast of Colors and Their Applications to the Arts* [1] was once considered one of the 12 most important books on color [2].

Chevreul's Life and Work

Born in Angers in 1786, Michel-Eugène Chevreul (Fig. 1) came to Paris when he was 17 years old and was appointed at the National Museum of Natural History as an assistant in charge of the chemical analysis of samples, thanks to a letter of recommendation from Vauquelin. Interestingly, his career as a chemist was determined by a sample of soap Vauquelin asked him to analyze. Indeed, the nature of animal fat was still unknown at the time. After several years of research, he published a book that gave him his fame as a chemist [3]. His discovery of the different acids contained in animal fat eventually led to important improvements in the field of industry, in particular in candles, as it made it possible to make candles shedding more light and less smoke. As he was also very interested in epistemological issues, he dedicated another book, 1 year later, to explain which method enabled him to make his discoveries [4].

In 1824, thanks to his fame as a chemist, Chevreul was appointed at the Gobelins Manufactures, as Director of the Dyeing Department. The Gobelins usually appointed chemists, as one of the main tasks of the Department of Dyes was

Georges Roque has retired.

Chevreul, Michel-Eugène, Fig. 1 Michel-Eugène Chevreul (1786–1889) at the approximate age of 50. (Lithograph by Nicolas-Eustache Maurin, 1836, engraving by Conrad Cook)

to take care of the ► [dyes](#) of wools and silks used by the three manufactures, the most important being that of tapestries (Gobelins). The Director of the Department had indeed among other tasks that of looking after the quality of the wool (that had to be cleaned from grease and bleached) and the quality of the ► [dyes](#) according to their stability, their brilliance, and the kind of cloth to which they had to be applied (basically wool, silk, and cotton). Another important issue was that of color classification.

Before focusing this essay on the law of simultaneous contrast of color, it is worth noting the wide range of interests Chevreul had for colors. He himself suggested a classification of his work on color. The two main categories are (a) means of naming and defining colors and (b) ► [dyes](#) ([5], p. 121).

Means of Naming and Defining Colors

After being appointed at the Gobelins, Chevreul quickly realized that when the weavers needed a nuance of color, they used to show a sample of

Chevreul, Michel-Eugène, Fig. 2 Chevreul's chromatic hemispheric construction. (From Chevreul [1])

thread for matching, which was very empirical. For this reason, Chevreul felt it necessary to create a general classification of colors he first called “hemispheric construction” (Fig. 2), which, interestingly, is a black-and-white model (published in [1]). The circle is divided into 72 hues. Each of the 72 radii is divided into 20 segments, numbered from 1 to 20, corresponding to the scale of lightness, from the center (white) to the diameter (black). The third dimension is given by a quadrant perpendicular to the circle (unfolded in Fig. 2), corresponding to a saturation scale, and divided in 10 sections. This abstract system of color classification is the most complex realized at the time (1839) and permitted differentiating a great number of nuances: the 72 main hues of the circle with their 20 grades of lightness already give 1440 different nuances, to which must be added the 10 grades of saturation on the axe of the quadrant, that is, $1440 \times 9 = 12,960$. So the general amount of nuances is $14,400 + 20$ gray along the 10th radius, that is, 14,440. For a more precise account of Chevreul's color classification and a reply to the critiques made to it – in particular the fact that he would have confused lightness and saturation – see [6, 7], pp. 163–172.

Aware of the importance of color classification beyond the case of the Gobelins, Chevreul went on working on the topic and published several important books containing, unlike the 1839 black-and-white hemispheric construction,

Chevreul, Michel-Eugène, Fig. 3 First chromatic circle containing pure hues. (From M.-E. Chevreul, *Cercles chromatiques de M.-E. Chevreul*, 1861)

beautiful color plates [8–10]. At the 1851 *World Exposition* in London, Chevreul's chromatic circle was awarded a Great Medal. (Fig. 3) shows a further publication.

Dyes

In his classification of his own work on color, Chevreul divided the dye section into three parts: all that is relative to the simultaneous contrast of colors, all that concerns what he called the principle of color mixing (which corresponds to what is known today as chromatic assimilation), and finally chemical researches.

Indeed, long before being appointed by the Gobelins, Chevreul had worked on natural tints; on indigo, for instance, he devoted a dozen papers, the first being published in 1807, when he was 20 years old [11]. His interest for animal fat also helped him to work on the process of degreasing and of bleaching ► **dyes**, to which he devoted numerous papers.

Although Chevreul's work on color covers many aspects, his most important contribution to color is his law of simultaneous contrast of colors, as expounded in his book translated into English under the title *The Principles of Harmony and Contrast of Colours and Their Application to the*

Arts (1st edition in French, 1839; 1st English translation, 1854). Its starting point was a complaint from the weavers of the Gobelins against the dyers of the Department of Dyeing that he directed. The complaint was in particular about the black samples of wool used for the shades of blue and violet draperies. As a chemist, Chevreul first tested the wools dyed in black in his workshop and compared them with those dyed in the best places from London and Vienna. After a careful comparison, he realized that the quality of the dyed material was not in question. This led him to raise a brilliant hypothesis: the lack of strength of the blacks was not due to the dyes or their uptake but was a visual phenomenon related to the colors juxtaposed to the blacks. This new discovery was all the more surprising as Chevreul, being a chemist, was not prepared to admit that the cause of the phenomenon he observed “is certainly at the same time physiological and psychological” ([12], p. 101).

Indeed, Chevreul realized that it is not the same to look at a sample of color when isolated and when juxtaposed to another contiguous one. In the latter case, the two samples appear different from when seen in isolation. This is the most general effect of the law of simultaneous contrast of colors that reads, “In the case where the eye sees at the same time two contiguous colours, they will appear as dissimilar as possible, both in their optical composition and in the strength of their colour” ([1], § 16). Chevreul made it very clear in one of the plates (Fig. 4): O and O', as well as P and P', have exactly the same degree of lightness; however, the perception of the samples differs when they are seen in isolation and juxtaposed to another sample of a different degree of lightness. The bottom of the same plate shows an effect known as “Chevreul's illusion”: each stripe (except the two extremes) being lighter than the following (when seen from left to right), a double effect is produced, because the left half of each stripe will appear darker and the right half lighter, due to the influence at the edges of the preceding and following stripes. (For Chevreul's illusion, see [13].)

Chevreul's demonstration is valid for hues as well as for lightness. For what concerns hues, the main definition of the law of contrast reads,

Chevreul, Michel-Eugène, Fig. 4

Illustration of the contrast of lightness. (Redrawn detail from original figure in Chevreul [1])

If we look simultaneously upon two stripes of different tones of the same colour, or upon two stripes of the same tone of different colours placed side by side, if the stripes are not too wide, the eye perceives certain modifications which in the first place influence the intensity of colour, and in second, the optical composition of the two juxtaposed colours respectively. Now as these modifications make the stripes appear different from what they really are, I give to them the name of *simultaneous contrast of colours*; and I call *contrast of tone* the modification in intensity of colour, and *contrast of colour* that which affects the optical composition of each juxtaposed colour. ([1], § 8)

The principle is exactly the same as for lightness: the modification consists in an exaggeration of difference. Yet, in the case of hues, what means exaggeration of difference? Chevreul's starting point is the concept of complementary colors, that is, colors considered as the most opposed. According to the knowledge of the time, Chevreul considered as complementary the following pairs of colors:

Red is complementary to Green, and vice versa;
Orange is complementary to Blue, and vice versa,

Greenish-Yellow is complementary to Violet, and vice versa

Indigo is complementary to Orange-Yellow, and vice versa. ([1], § 6)

So the modification perceived when seeing juxtaposed colors consists in perceiving each color as slightly tinted with the complementary color of the juxtaposed one. This is the clever way Chevreul had to understand and solve the problem raised by the weavers when complaining of the bad quality of the blacks dyed in the Dyeing Department of the Gobelins. When seen in isolation, the blacks are perfectly black, but when seen juxtaposed to violet, they are slightly tinted with the complementary color of violet, that is, yellow, and will look accordingly yellowish. In order to solve the problem, Chevreul suggested the weavers to mix a few threads of violet with the blacks, so that they neutralize the effect of yellow and make accordingly the blacks look blacker!

A particular case must be mentioned: what happens when the two juxtaposed hues are complementary, for example, red and green? According to the law of simultaneous contrast, the red will be slightly tinted by the complementary color of green, that is, red, and will be perceived as redder. Conversely, the green will be slightly tinted by the complementary color of red, that is, green, and will be perceived accordingly as greener. In this case, the two hues are not

modified in the sense of a transformation of the hue itself but enhanced.

Regarding the importance of Chevreul's law of ► **color contrast**, some authors hold that it was not original since other scientists before him, like Prieur, had already discovered the law of ► **color contrast** ([14], p. 306; [15], p. 140). It is true that Prieur and others had already discovered similar phenomena. However, it might be recalled that Chevreul fairly acknowledged what he borrowed from other authors (including Prieur) since he devoted a chapter to the issue of the relationship between his experiments and those made by others before him ([1], § 120–131). For him, indeed, his main contribution is *not* the “discovery” of the ► **color contrast** but the fact of classifying and structuring these phenomena well described by his predecessors but considered as belonging to one single class, when Chevreul proposed to carefully distinguish different kinds of contrast, so that the simultaneous contrast is just one of them. It is defined as follows:

In the *simultaneous contrast of colours* is included all the phenomena of modification which differently coloured objects appear to undergo in their physical composition and in the height of tone of their respective colours, when seen simultaneously. ([1], § 78)

Besides simultaneous contrast, Chevreul distinguishes *successive contrast*, which includes all the phenomena that are observed when the eyes, having looked at one or more colored objects for a certain length of time, perceive, upon turning them away, images of these objects offering the complementary color of that which is proper to each of them ([1], § 79). This distinction is very useful and helped to differentiate phenomena until then confused; it is still in use, even though simultaneous contrast is often related today to chromatic induction, while successive contrast is generally associated with chromatic adaptation; for this reason, the concept of afterimages is often used today instead of that of successive contrast.

Chevreul also distinguished a mixed contrast ([1], § 81), which combines simultaneous and successive contrast; it occurs, for instance, when, after having looked at one color for a certain length of time, another color is looked at. In this case, the resulting sensation is a combination of

the second color and of the complementary of the first one. Finally, Chevreul also added later a fourth contrast, the *rotary contrast* obtained with colored spinning disks [16].

It is out of the scope of this essay to discuss the main critiques addressed to Chevreul in particular the fact that he would have confused mixture of lights and mixture of pigments or simultaneous contrast and assimilation (for a full account of these issues, see ([7], pp. 93–102)).

Chevreul's Influence on Artists and Artisans

Another striking fact is the huge influence Chevreul had on generations of artists and artisans, even before the publication of his book on simultaneous contrast in 1839, thanks to the public lectures he gave and that were attended by painters, but also wallpaper fabricants and many other color practitioners. The range of his influence is indeed impressive, from tapestry to stained-glass restoration, shop signs to gardening. Many reasons explain the success of his book, soon printed out (the second French edition, published in 1889, as well as the third one, published in 1969, have also been quickly printed out). One is that by dedicating a copious volume to this matter, he gave wide public access to phenomena until then discussed only in specialized scientific journals. Another is that by meticulously studying the applications of his law to almost all the fields of art and crafts, he moved from pure science to applied science and addressed himself to almost all those who use color. One more reason is that by addressing the issue of how to match and harmonize juxtaposed colors, he provided artists and artisans with practical rules and harmony advices quite useful in the situation painters and tapestry-makers are constantly confronted with, that is, using juxtaposed colors. Finally, as he had a great prestige as a scientist, the color harmonies he proposed were avidly read and followed by artists anxious of matching their colors and enhancing them. Interestingly, unlike what is generally assumed ([17], p. 196), Chevreul was not a partisan of the harmony of color contrast and never recommended painters to juxtapose

complementary colors on their canvases. The reason is that for him the effect of simultaneous contrast always occurs naturally so that if a painter tries to imitate what he sees, he will exaggerate the effect instead of rendering it accurately.

Even though Chevreul's teachings gave rise to misunderstandings, he nevertheless had an enormous influence on painters, from the 1830s up to the beginning of abstract painting. If his influence on Delacroix remains controversial, it is important for ► [impressionism](#) and crucial for ► [neo-impressionism](#) and van Gogh. From the 1880s onward, his work was challenged by more up-to-date theories (Helmholtz, Rood); however, he still had an influence, in particular on Delaunay but also on color music, due to the usefulness of the rules of successive contrast he established. Even the most important books still used in color teaching (Itten and Albers) owe a lot to Chevreul. For a comprehensive account of Chevreul's influence on artists, see [7]. His huge importance on artists must not lead to overlook that his color theories also had a great influence on scientists, in a wide range of fields, including archeology, stained glass restoration [7, pp. 209–212], ophthalmology and anthropology [18].

Associative and symbolic meanings of culturally
the most significant color categories.

Notions on Color in Early China

In Western thought color has been associated with light (at least since the time of Aristotle), whereas in ancient China color was linked to the dichotomy colored/uncolored – either by nature, or artificially – and unrelated to the presence or absence of light. Colors were considered the property of the object itself and were therefore “perceived not as abstract concepts but as concrete substances, endowed with rich meanings” [1]. For instance, color correspondences applied to sacrificial animals during the Late Shāng 商 (ca. 1250–1046 BCE) period required that white, red, and multicolored animals were sacrificed in the ancestral cult; black sheep were used in the rain-making ritual; yellow animals were particularly addressed to the cosmic spirits of the earth and the cardinal directions [2]. Multicolored animals were inferior to those of pure color because they symbolized a ritual impurity. These first attempts of color categorization are registered in

Shāng oracle bone inscriptions (*jiǎgǔwén* 甲骨文), the earliest written records of Chinese civilization.

Color symbolism was directly related to the material from which the color was derived. Red was regarded as a “life-giving” color, a magical return of the soul: evidence from burial sites suggest that red ochre during Paleolithic and cinnabar from Neolithic times to the Hàn 漢 dynasty (206 BCE–220 CE) were interred along with the corpses [3]. Traces of cinnabar, applied with a writing brush, occur in the incised lines of writing on Shāng oracle bones.

Unknown in ancient Egyptian painting and the early Mesopotamian cultures, cinnabar, the naturally occurring mineral form of mercuric sulfide, was one of the most precious materials and significant colorants in ancient China. Finely ground and mixed with glue, it makes a brilliant and glowing red pigment. Another “magical” property of cinnabar, which is the color of blood and thus of life itself, is that it can be transformed into mercury, or quicksilver, a “living” metal. Mercury was also employed in early burial practices in China. The floor of the tomb of the First August Emperor of Qín 秦始皇帝 (r. 221–210 BCE) is said to contain a topographical model of the world with all the rivers running in mercury. Therefore, cinnabar had a profound religious significance in ancient China; it was believed to be a substance by which the forces of life and the cosmos could be controlled.

By the fourth century BCE, belief in the revitalizing function of cinnabar and mercury in burial practices had given rise to the idea of an elixir of immortality. Just as the living metal quicksilver symbolized the quickening of the soul, so the imperishable metal gold came to symbolize immortality. To attain immortality, the body must be transformed to a gold-like state. Early means of effecting this transformation involved consuming an herb of immortality or eating from vessels of gold. Perhaps because naval expeditions and golden dishes were out of the reach of most, there also arose the belief that gold and silver could be fabricated from other substances. The most important of these was cinnabar, solid and in its liquid state as mercury. This artificial gold could then be used to create the elixir of

immortality. Two fundamental beliefs of Daoist alchemy are, then, that the body can be transformed to a gold-like state, and that gold can be made from other substances, especially cinnabar. Cinnabar was so central to Daoist alchemy that the Chinese word for elixir, *dān* 丹, is the same word as cinnabar [4]. Present-day Chinese consider red auspicious.

One of the main characteristics of the psychology of an ordinary ancient individual is the concreteness of thinking associated with labor processes. In ancient China, these processes included pottery, bronzes, lacquerware, and textile manufacturing.

Implements of coloration were used already in the Neolithic period. Since the 1920s, Chinese and western archaeologists have discovered many sites of the Yǎngsháo 仰韶 “painted pottery” culture in central and northwest regions. The most distinctive wares with black-and-purple decoration were produced during the Bǎnshān 半山 phase of the Mǎjiāyáo 馬家窯 culture (Fig. 1).

The subterranean army of several thousand life-size terracotta soldiers, horses, and war chariots, under excavation since 1974 from the site near the supposed burial chamber of the First August Emperor of Qín, has become famous as one of the grandest archaeological discoveries of the twentieth century. Pictures of gray terracotta warriors, created to serve China’s first emperor in

the afterlife, have become known all over the world. Today it is the terracotta itself that determines the chromatic impression made by the excavated clay warriors, but originally the terracotta figures were colorfully painted (Fig. 2).

Red and green were the most frequent colors, followed by the numerous brownish and pinkish nuances ranging from reddish and violet-brown to pink tones and off-white. Inorganic materials of natural and synthetic origin were used as pigments. Remarkable is the generous use of pigments extracted from precious materials like cinnabar, malachite, and azurite. Before the pigment layers were applied, terracotta sculptures and their equipment (made of bamboo, wood or fabric) were coated with two very thin layers of East Asian *qī* 漆 lacquer, whereas bronze sculptures were painted directly without lacquer priming [5].

Lacquer is a natural product that comes from the sap of the lacquer tree. Out of 25 existing species of the lacquer tree, 15 grow in China. One of the earliest excavated lacquered samples is a wooden bowl with red cinnabar lacquer of Hémùdù 河姆渡 culture was found in Yúyáo 余姚, Zhèjiāng 浙江 (ca. 6000–ca. 5000 BCE) [1]. Lacquer was often applied on objects made of wood, leather, bone, and textiles.

As is commonly known, China is the birthplace of sericulture; silk was used there as early as six thousand years ago. Other textiles existed, such as ramie produced from nettles, hemp from mulberry, abutilon from mallow, and some may even predate silk [6]. The art of dyeing naturally developed along with the creation of textiles. The surviving examples of the Warring States 戰國 period (475–221 BCE) textiles reveal a high-level dyeing technique of vegetable and mineral dyes, decorated with painting and embroidery (Fig. 3). They are dyed in such a variety of red, yellow, green, blue, and purple shades that the color lexicon of that time was unable to convey all the nuances of the obtained hues.

Unsurprisingly, the modern Chinese word for “coloration” includes the morpheme (*cǎi* 彩 < 採) that was originally applied to embroidery (when the yarns were selected according to their color) and implied the meaning “combined by interwoven multicolored threads.” As regards the morpheme “color” (*sè* 色), it originally referred to

Chinese Color Language, Fig. 1 Funerary urns. Bǎnshān type red earthenware with black and purple painted decoration. The bold linear decoration is executed with a soft brush. Production date ca. 2650–2350 BCE. Ht.: 34–36 cm. (© The Trustees of the British Museum)

“facial expression,” “complexion,” “outward appearance,” and is used to describe naturally or artificially colored objects in China’s first etymological dictionary, the *Shuōwén jiězì* 說文解字 of Xǔ Shèn 許慎 (ca. 100 CE).

“Primary” and “Secondary” Colors

NB: It should be immediately warned that:

- (a) Colors described hereinafter do not always coincide with the coloristic meanings accepted in European art.
- (b) The meanings of many color names have shifted. “Each individual shift, when it occurs, has a clear connection with the older meaning, if further shifts occur, they are increasingly likely to obscure or supersede the earlier meanings” [7]. The definitions of color names used here are those of Modern

Chinese Color Language, Fig. 3 Silk textiles from a tomb at Mǎshān 馬山, sixth to third century BCE. Left: detail of the embroidered sleeve of a garment in the sixth of

thirteen layers of wrappings and clothing. Right: detail of embroidered phoenix decoration on the quilt or cover forming the fourth layer [5]

Standard Mandarin (henceforth MSM), that is, contemporary Chinese from the twentieth century onwards.

The first proper color categorization one can see in the literature of the Eastern Zhōu – Hàn period, which is full of references to the “five colors” (*wǔ sè* 五色): “white” *bái* 白, “red” *chì* 赤, “yellow” *huáng* 黃, “grue” (green-and/or-blue) *qīng* 青, and “black” *hēi* 黑. The denotations of these terms are difficult to trace [8].

The texts referring to the five colors were probably influenced by the *wǔ xíng* 五行 theory, conventionally translated as the theory of five elements, or the theory of five agents, or which assumed complex interrelationships among the five elements, wood (Wd), fire (F), soil (S), metal (M), and water (W), the five directions, the five colors, the five tastes, the five smells, the five internal organs of the body, etc. (see Table 1). The pentamorous structure is often seen as the 2 + 3

formula that presumably represents the *yīn-yáng* 陰陽 duality and the triad of Chinese thought, Heaven-Earth-Humanity (天、地、人). Thus, the Chinese of that time “had theoretical reasons for believing that there *had* to be five colors, and their statements to this effect cannot be taken as direct evidence about their language (they were, after all, capable of tacking on a fifth direction, ‘middle’, to fit to the theory)” [9].

The correspondences shown in Table 1 are only a few out of many more; they were the commonplaces of thought in growing measure from the mid-third century BCE onwards and may be found in varying degrees of completeness in most of the ancient texts. They are full of discrepancies and may be stated in different ways in the same text.

Remarkably, the existence of the five-color gamut in ancient China is also confirmed by the archaeological discoveries. In the 1960s there were found 15 vessels *túlú* 圖盧, color-containers

Chinese Color Language, Table 1 Pentamorous symbolic correlations

Element	Wood (Wd)	Fire (F)	Soil (S)	Metal (M)	Water (W)
Season	Spring	Summer	Late summer	Autumn	Winter
Direction	East	South	Middle	West	North
Color	Green/blue	Red	Yellow	White	Black
Directional animal	Grue Dragon	Vermilion Bird	Yellow Dragon	White Tiger	Dark Warrior
Human psycho-physical function	Vision	Thought	Speech	Hearing	Demeanor
Source of happiness	Physical and mental health	Fulfilling to the end the will of heaven	Richness	Love of virtue	Longevity
Taste	Sour	Bitter	Sweet	Acrid	Salt
Smell	Goatish	Burning	Fragrant	Rank	Rotten
Planet	Jupiter	Mars	Saturn	Venus	Mercury
Weather	Wind	Heat	Thunder	Cold	Rain
Animal category	Scaly	Feathered	Naked	Hairy	Shell-covered
Viscera	Spleen	Lungs	Heart	Kidneys	Liver
Affective state	Anger	Joy	Desire	Sorrow	Fear

assigned to the Late Shāng – Western Zhōu 西周 period. Most of these containers are made in bronze and vary from cuboid to round and triangular in shape; each of them has three to five tubular receptacles for the pigments. In five of these containers, residues of pigments were found in the bottom of the tubes, and these have been identified as white, black, red, green, and yellow powders. A small scraping from the bottom of the four receptacles of one of the containers underwent spectroscopic analysis, and the results showed that the following substances were present in a large amount: white powder, calcium oxide or calcium carbonate; black powder, carbon black or graphite; red powder, iron oxide; green powder of compound of copper [10].

Five elements constantly interact in some 20 combinations and permutations affect the cosmos, the natural world, and the world of human affairs. The most culturally significant arrangements are the “mutual production” (*xiāng shēng* 相生) and the “mutual conquest” (*xiāng kè* 相剋): the former arrangement (WdFSMW) was applied to illustrate life cycle, while the latter arrangement (WdSWFM) was extended to dynastic transitions. If a ruling dynasty’s emblem was fire, the honored direction was the south and the worshipped color

was red, the overcoming dynasty’s emblem would become water, therefore the honored direction would be the north and the worshipped color would be black. As a whole, the system is bound up with Chinese astronomy, astrology, geomancy, and also with a branch of ancient Chinese medicine.

Today in Beijing, in the entrance part of the Forbidden City (*Zijincheng* 紫禁城), within Zhōngshān park 中山公園, one can see the Altar to the Gods of soil and grain (*Shèjītán* 社稷壇). Built in 1421, it was used for performing sacrifice ceremonies by the emperors of the last two dynasties that ruled China. The altar is a small, three-tiered square platform: according to the ancient Chinese mytho-geographical and cosmographic principle, “heaven is round and the earth is square” (*tiān yuán dì fāng* 天圓地方). The surface of the Altar is paved with five types of soils, distributed into sections according to the appropriate cardinal directions (Fig. 4). The soil in five colors symbolizes the traditional idea that “all under heaven belongs to the emperor” (*pǔ tiān zhī xià, mò fēi wáng tǔ* 溥天之下, 莫非王土) and the everlasting endurance of the dynastic world.

In Confucian writings, the colors of the five elements are orthodox or conventional and

Chinese Color Language, Fig. 4 The altar of five-colored soil (五色土) in Beijing. (Photo by Victoria Bogushevskaya)

referred to as “primary,” “correct” (*zhèng* 正), whereas the colors generated in the process of the mutual conquest of the respective elements are called “intermediate” (*jiàn* 間) and are considered subordinate. The original meanings of the “secondary” colors are “reddish-pink” *hóng* 紅, “yellowish-green” *lǜ* 綠, “purple-red” *zǐ* 紫, “turquoise” *bì* 碧, and “brown” *liúhuáng* 騮黃. The first three color names are textile terms, the penultimate one is semantically related to jade and the latter one to horse [8] (Fig. 5).

Technically, there was such a great variety of the intermediate tints at that time, that any shade lighter or darker than the “standard pure” color could be called “intermediate,” and therefore automatically considered secondary and of a low rank. The five “primary” colors were advocated by the *Yīn-Yáng* 陰陽 scholars during the Warring States period and later by Confucians, as they simply had to adapt contemporary advanced dyeing knowledge to their theory, and the list of the so-called secondary colors inevitably appeared.

It is important to note that the word for “red” (*chì* 赤) in the five-agent theory is different from the word for “cinnabar” (*dān* 丹). Alchemy was condemned by the Confucian scholars at court as early as the first century BCE. From a Confucian point of view, alchemy was at best mere fakery and illusion, and at worst, a waste of money, talent, and lives. The Confucianists had no interest in the physical manipulation of pigments; their

Chinese Color Language, Fig. 5 Canonical colors' mixing order [8]

approach to color instead made symbolic and moralizing use of hue, that is, “the attribute of colors that permits them to be classed.” Color as hue is charged with social and political significance. In contrast with Daoist notions of color as a controlling substance, the Confucian belief is that color requires control [4]. The distinguishing between “primary” and “mixed” colors inspired “noble versus humble,” “good versus evil,” and other symbolic meanings.

It is interesting to note that the names of the dress decorations used by ancient painters and embroiders depend on the combinations of five colors: *wén* 文 is a decoration which is composed of blue-green and red, *zhāng* 章 – of red and white, *fū* 黼 is an axe-pattern decoration with interlacing black and white colors, *fú* 黻 is a 亞-pattern decoration with interlaced black and blue-green colors, *xiù* 繡 is an embroidery decoration mixed with five colors (blue-green, red, white, black, and yellow) [11].

As regards the descriptions of obtained shades, ancient sources often provide very limited information. We can read descriptions like:

Three dips produce [what is called] *xūn* 纁; five dips make [what is called] *zōu* 緅; and seven dips result in [what is called] *zī* 緇 [11].

One, therefore, needs to investigate what pigment or dye was used, with or without mordants.

Color became an indispensable element of official decrees on clothing in imperial China (from the Qín 秦 dynasty, 221–207 BCE, to the Qīng 清 dynasty, 1644–1911) to distinguish ranks and contribute to the stability of social hierarchy and bureaucratic systems. Each dynasty regulated pattern, color, material, and the number of patterns and accessories used for coronets, costumes for various occasions, and accessories that people of different ranks could wear [12]. The “primaries” were limited to higher-ranking officials, for upper clothing, and headgear, while the “secondaries” must be used by those of lower rank and for clothing the lower body [6]. There were also rules dictating the correct clothing for each season and when these seasonal wardrobe changes should be made.

As regards the concrete dyestuffs, a Táng-dynasty (618–907) text is more specific. The *Táng liùdiǎn* 唐六典 (Compendium of administrative law of the six divisions of the Táng bureaucracy) states that court dyers recognized five official colors: red from madder, blue/green from indigo, yellow from gardenia, “black” from acorns, and purple from gromwell. Except for acorn’s gray-brown-black range, these were the colors used to dye official robes the appropriate rank colors and, with the exception of purple, they were the five colors associated with *wǔ xíng* 五行 [13].

During the golden age of alchemy, from the third century BCE to the ninth century CE, painting was dominated by the mineral pigments. Several connections existed between alchemy and painting in mineral colors. Many of the same mineral substances served as ingredients in the elixir of immortality and as painting pigments. These include cinnabar, vermilion, malachite, azurite, realgar, minium, orpiment, ochre, gold, silver, lead, graphite, clamshell, and alum. Many of the scientific techniques used to process these materials for use in alchemy and painting were the same, such as grinding, heating, washing, and suspending. Moreover, alchemy and painting were both referred to by synecdochical names. While alchemy was called “the art of yellow and white” (*huáng bái zhī shù* 黃白之術), in reference to the desire to produce gold and silver, painting

was called the art of “red and blue,” or literally, “cinnabar and azurite” (*dānqīng* 丹青). From the Daoist point of view, both painting and alchemy were transformative and magical arts that could be used to control the forces of life [4].

The color grading system of the last two dynasties to rule China, the Míng 明 (1368–1644) and Qīng 清 (1644–1911), involved more grades and colors than those of previous dynasties. Color restrictions were applied to the emperor’s attire for particular occasions and also to the use of colors for clothing and utensils appropriate to various degrees of status within the imperial household. For example, in the formal court attire used only on ceremonial occasions, the emperor would wear blue for sacrifices at the Altar of Heaven, red at the Altar of the Sun, light blue for sacrifices to the moon, and yellow for those to the earth. Yellow was also the default color for ceremonies where none was stipulated and was furthermore the color associated with the Qīng dynasty. Yellow and green porcelain glazes were used in different combinations on bowls and dishes according to the imperial rank of the user [6]. Color symbolism has been omnipresent at the palaces and temples.

The last emperor Pǔ-yí 溥儀 (1905–1967) of the Qīng dynasty describes the dominance of the imperial yellow in the following way: “The glazed tiles were yellow, my sedan-chair was yellow, my chair cushions were yellow, the linings of my hats and clothes were yellow, the girdle round my waist was yellow, the dishes and bowls from which I ate and drank, the padded cover of the rice-gruel saucepan, the material in which my books were wrapped, the window curtains, the bridle of my horse... everything was yellow. This color, the so-called ‘brilliant yellow’, was used exclusively by the imperial household...” [14].

Purple, originally considered to be a “secondary” color, was nevertheless added to the palette of colors to indicate very high rank presumably in the second century BCE, although not without protest from conservative Confucian scholars. Extracted from the roots of a gromwell plant, *Lithospermum erythrorhizon* (*zǐcǎo* 苺草/紫草), reddish-purple had been one of the most popular colors until the Former Hàn period

(206 BCE–9 CE) [13]. The ancient states of Lái 萊 and Qí 齊 were famous for the production of this plant [8]. The gromwell-dyed silk was costly, and the dye process required considerable skills. The color was derided by Confucian scholars as example of the luxury and frivolity that they deplored [13]. Furthermore, Confucius was original of the state of Lǔ 魯, a long-time enemy of the states of Lái and Qí. Another possible reason is that purple was the color associated with Daoism (see section “Purple”).

A pigment only known in China is the bright bluish-purple, a man-made barium copper silicate, which was widely used until the end of the Hàn dynasty (220 CE). Rediscovered in 1983, it is known as Chinese Purple or Hàn Purple (*Hàn zǐ* 漢紫) today and is one of the most frequent colors of the Qín Shǐ Huángdì’s terracotta army. It is not known if artificial barium copper pigments were produced before the Qín dynasty [15].

Daoism was a strictly Chinese religion which had originated and flourished entirely on Chinese soil. The robes of the Daoist priests were rather drab and plain; but for grand occasions, such as special funeral rites, the high priests wore richly decorated copes. By contrast, Buddhism was a foreign religion in China, introduced from India by way of Central Asia; as such, during the Middle Ages it had even been proscribed for a time, along with Manichaeism, Nestorian Christianity, and other foreign faiths [16]. With time, Buddhism absorbed many Chinese cultural elements and became Chinese Buddhism.

Just as a monk’s robe *jiāshā* 袈裟 (from the Sanskrit *kāṣāya*) distinguished him from an official, variations in the robe also distinguished different types of Buddhist monks. A common term for monks in medieval texts is the “black-robed ones” (*zīyī* 緇衣). And when referring to monks and laymen, Buddhist texts commonly use the expression “the black and the white” (*zībái* 緇白) [17]. The historical Buddha had cautioned his followers against luxurious living. Accordingly, when his monks were presented with valuable silks or discarded robes, they would simply cut these up into small squares and reassemble them without regard to pattern, to fulfill the spirit if not the strict letter of the law [16]. In medieval China, monks

from different regions were recognized by the color of their robes – pitch-black (*hēi* 黑) in the Jiāngnán 江南 region, brown (*hè* 褐) in the area around the capital at Kāifēng 開封, and so on. After the tenth century CE, the color of robes was gradually standardized. Now Chinese Buddhist monks usually wear black or gray robes [17].

Chinese Mnemonic Phrases for the Colors of a Rainbow

Many languages have a mnemonic phrase to help remember the order of the seven colors of the rainbow. We know the English “Richard-of-York-gave-battle-in-vain” or the Russian “Каждый (красный ‘red’) охотник (оранжевый ‘orange’) желает (жёлтый ‘yellow’) знать (зелёный ‘green’), где (голубой ‘light blue’) сидит (синий ‘blue’) фазан (фиолетовый ‘purple’)” [“Every hunter wants to know where the pheasant’s hiding”], where the initial letters of each word correspond to the rainbow color sequence.

In Chinese, there are vague analogs. The first one is related to the so-called “folk” version of the five elements’ sequence, “*jīn-mù-shuǐ-huǒ-tǔ*” 金木水火土 (MWdWFS). The phrase has the 2 + 3 prosodic structure and is therefore easy to memorize. As a result, the correlative colors automatically emerge in a speaker’s mind.

In 1853, Zhāng Fúxī 張福僊 translated *Guāng lùn* 光論 (*On light*), which was the earliest systematic study on chromatic dispersion in China [18]. However, the color terms he used never crystallized into a mnemonic phrase. Instead, the phrase that is taught at school today derives from the line of a poem written by Máo Zédōng 毛澤東 in the 1930s: “*chì-chéng-huáng-lǜ-qīng-lán-zǐ*” 赤橙黃綠青藍紫 “red, orange, yellow, green, blue, blue, purple” [19].

Symbolism of the Main Color Categories

Studies on Chinese color terminology are carried out from different perspectives (historical-cultural, participation of a term in

word-formation, psycholinguistic analysis, usage frequency, etc.) and often aim to verify the evolutionary stage encountered in contemporary color vocabulary along with the list of the so-called basic color terms. These issues need not be addressed here. For the convenience of comparison with other languages, this section aims to describe symbolic and figurative meanings of the most commonly used color categories in MSM. Some of these meanings can be cross-culturally similar, intuitively graspable or remote.

Each color category includes a wide range of shades. In addition to its cosmological symbolism (see Table 1), each category as well as the shades within the same category may have several different and sometimes mutually exclusive meanings. These meanings often originate from popular beliefs and philosophic systems.

Black

As a symbol, black stands for darkness, death, honor. “Dark-cool” *xuán* 玄 appears in old mythological and astronomical traditions. The mythical ancestor of the Shāng was a *xuánniǎo* 玄鳥 “black (dark-cool) bird.” “Although the north was associated with *hēi* 黑, the association with *xuán* 玄 may be older: the northern constellations (also regarded as a god) are called *xuánwǔ* 玄武 the ‘dark warrior’” [9].

In Buddhism, black symbolized “bad” in a sense of violating the principles of Buddhism. In the old Chinese calendar, unlucky days are black (*hēidàorì* 黑道日) [20].

In traditional theatre plays, the choice of color in face painting often derives from the written literature about the historical characters who appear on the stage. Bāo Zhēng 包拯, the famous judge from the Northern Sòng 北宋 dynasty (960–1127), was called “iron face” because he was impervious to bribery and influence. His stage counterpart, Judge Bāo, is now depicted with black and brown face paint [21].

If a woman’s hair is described as *wūyún* 烏雲 “raven-black clouds” this means that it is black and beautifully lustrous.

One of the five forms of ancient corporal punishment (the other four include cutting off the nose, cutting off the feet, castration, and

decapitation) is called *qíng* 黥 (the character contains the semantic determiner “black” 黑), “ink punishment,” in which the forehead was cut and marked with a black dye as a permanent mark [18].

In MSM, black has negative connotations. Examples include *hēixīn* 黑心 (“black heart”) “evil mind,” *hēishèhuì* 黑社會 (“black society”) “criminal underworld,” *hēihuò* 黑貨 (“black goods”) “contraband,” *hēikè* 黑客 (“black guest”) “hacker,” “cyber-terrorist,” *hēichē* 黑車 (“black vehicle”) “illegal taxi,” *hēiháizi* 黑孩子 (“black child”) “unregistered child” (a child whose birth means the birth quota has been exceeded), etc.

White

“White tiger” *báihǔ* 白虎 is the animal of the West. White is said to have been the symbolic color of the Shāng. In the seventh century, scholars who had not yet been appointed to posts wore white clothes. The God of Earth *Tùdishén* 土地神, worshipped in folk religion, is represented as an old man with a white face [3]. White was adopted by Buddhism to mean “good” [14].

On the Chinese stage, actors with white faces represent men who are cunning and treacherous. Cáo Cāo 曹操, the ruthless warlord in the Three Kingdoms stories, has the white face painted with cake makeup to conceal his deceitful nature. The purity of the white symbolically hides his evil intentions (Fig. 6) [21]. The idiom *chàng báiliǎn* 唱白臉 (“play the white-face”) means “to play the role of the villain.”

One should never wear anything white in one’s hair, as this is very unlucky. The west is not only the direction where the sun dies, but also where dead people are headed for. Funeral is *báishì* 白事 “white affair.” However, it is not quite correct to say that mourning is white *bái* 白. Mourning apparel was made of *sù* 素, a kind of unbleached sackcloth, which is a brownish-yellow rather than white [3].

“Pure white” *qīngbái* 清白 is an expression denoting a morally pure, stainless person. Hair color of an elderly person is *bái* 白 white, but a blonde person’s hair is *jīn* 金 golden or *huáng* 黃 yellow. “To give someone a white eye” (*gěi báiyǎn*

Chinese Color Language, Fig. 6 *Cáo Cǎo*, the ruthless warlord in the Three Kingdoms story, has the white face to conceal his deceitful nature [15]

給白眼), that is, to look askance and show the whites of one's eyes, is a gesture of disdain, disapproval or anger.

In some cases, *bái* 白 has nothing to do with color at all; the meaning may imply “in vain,” as in *báizuò* 白做 “waste one's energy,” “plain,” as in *báikāishuǐ* 白開水 “[plain] boiled water”, or “empty,” as in *báichī* 白痴 “idiot,” “imbecile.”

Red

This category used to be represented by the term *chì* 赤 that denoted a wide range of red hues, from dark red to dark orange and reddish-brown. Among other terms for red, *zhū* 朱 was also common enough to be a possible rival of *chì* 赤. From the *Táng* 唐 dynasty (618–907) onwards, *chì* 赤 was gradually ousted by *hóng* 紅 (originally one of the “secondary” colors with the meaning “pink”) and is a basic color term for RED in MSM

[22]. Nevertheless, *chì* 赤 continues to be used as an epithet of things in which the red color forms a natural or obvious mark of kind or class. The choice of *chì* 赤 or *hóng* 紅 in various expressions is of totally etymology-related lexical nature [14].

Related to the element “fire” and the color red *chì* 赤, South is the quintessence of the *yáng* 陽 male natural principle. The throne where the Emperor sat was always facing the South.

In Buddhism, “red dust” *hóngchén* 紅塵 means “the world of mortals” [20].

Hóng 紅 originally was a “secondary” non-*yáng* and therefore “womanly” “reddish-pink” color: *hónglèi* 紅淚 (“rosy teardrop”) “women's tear,” *hóngyán* 紅顏 (“rosy cheeks”) “a beauty.”

NB: “Red chamber” *hónglóu* 紅樓 means “women's living quarters” (the sheltered chambers where the daughters of prominent families resided and where a stranger was not allowed to enter), whereas “cinnabar-red gates” *zhūmén* 朱門 refers to wealthy homes.

Red is a life-giving and an auspicious color (see section “Notions on Color in Early China”). “Vermilion bird” *zhūquè* 朱雀 is the directional animal of the South. A red raven *chìwū* 赤烏 was the symbolic creature of the *Zhōu* dynasty, because the *Zhōu* identified themselves with the sun [3].

On the Chinese stage, a red-faced man is a holy person or a loyal general. *Guān Yǔ* 關羽, from the Three Kingdoms story, was referred to as having a “red ochre complexion,” and his stage makeup is a plain red *hóng* 紅 face [21]. The idiom *chàng hóngliǎn* 唱紅臉 (“play the red-face role”) means “to play the good cop.”

Red *hóng* 紅 means “successful,” as in *hóngyùn* 紅運 (“red fate”) “good luck” or “happiness,” as in *hóngshì* 紅事 (“red affair”) “wedding.” Place for a wedding ceremony is to be decorated with red. However, the bridal clothes, coverings for the marriage altar, and ornamental curtains, in use until about 1900, often presented a relatively softer red, which often faded out into a light golden tone, having been made of local vegetable dyes that were difficult to fix firmly [16].

Red is also held to be the color of wealth. In MSM, it has the meaning “profit,” as in *fēnhóng*

分紅 (“divide red”) “share out bonus,” usually distributed in *hóngbāo* 紅包 red envelopes.

Of the three gods of good fortune, highly regarded in Chinese folk religion, collectively known as “*Fú-Lù-Shòu sān xīng*” 福祿壽三星 (three stellar deities of happiness, wealth, and longevity), the one who confers high office and happiness wears a red robe; the one dressed in green blesses a family with children and wealth, while the third, who gives long life, is dressed in yellow or in white (Fig. 7).

Since red and green are the colors of life, their combination is especially significant. In one novel we read that a girl is as red as peach blossom and ripe for love (*táo hóng* 桃紅), while others are as green as willows (*liǔ lǜ* 柳綠) and can only be pitied (“pity” is a word that men often use when they are describing their feelings for young women). The idiom “lanterns red, wine green” (*dēng hóng jiǔ lǜ* 燈紅酒綠) describes the way of life in low pubs [3].

In MSM, red *chì* 赤 can also mean “bared,” as in *chìzú* 赤足 (“*chì* + foot”) “barefooted,” or “sincere,” as in *chìxīn* 赤心 (“*chì* + heart”) “sincerity.”

Red is associated with revolution and communism. With certain Chinese expressions, the word *red* does not help to convey the meaning in English. For example, *yòu hóng yòu zhuān* 又紅又專 “both red and expert” is not as helpful as

“both socialist-minded and professionally qualified.”

A common term for convicts in imperial China is the “red-ochre-robed ones” (*zhěyī* 赭衣). Convict’s garb was of reddish-brown color, collarless and with raw edges [18].

NB: Black tea is “red tea” *hóngchá* 紅茶 for Chinese, as the reference is the reddish-brown color the brewed tea liquid obtains, whereas Europeans refer to the color of the dry tea leaves. Brown sugar is *hóng* 紅 red or *chì* 赤 red [22]. If envious, one becomes *yǎnhóng* 眼紅 “red-eyed.”

Yellow

The coupling of “yellow” *huáng* 黃 and “middle” *zhōng* 中 (China is the “Middle Kingdom,” *Zhōngguó* 中國) is no doubt connected with the annual deposit of loess from the Gobi on the North Chinese plains, which then turn yellow; and this too was the color of the Emperor who ruled the Middle Kingdom. On the one hand, it was thought that the emperor was located in the center of the five directions. On the other hand, yellow was considered as the color of the sun: just as there cannot be two suns in the sky, there cannot be two emperors in a nation [12].

“Yellow Emperor” *Huáng-dì* 黃帝 was the mythical Emperor, but it was not until 618 CE that reddish-yellow *chihuáng* 赤黃 was accepted

Chinese Color Language, Fig. 7 From left to right: God of Wealth (nineteenth century Ht.: 24.40 cm), God of Happiness (eighteenth century Ht.: 25.40 cm), God of

Longevity (eighteenth century Ht.: 10.5 inches). (© The Trustees of the British Museum)

as the fitting color for the Imperial Majesty; hitherto red had been the preferred color [3].

The severe regulations for the costume of the Qīng dynasty that were promulgated in 1759 and enforced in 1766 – described, with pictures, in the *Huángcháo lǐqì túshì* 皇朝禮器圖式 (illustrated precedents for the ritual paraphernalia of the Qīng court) – required that the emperor and empress should wear robes of pure clear yellow *míng huáng* 明黃 “bright yellow” for any special occasions (Fig. 8), except for certain great annual sacrifices when the emperor’s dragon robe had to be of a special color appropriate to the particular occasion (see section ““Primary” and “Secondary” Colors”). Yellow robe with lack lower sleeves and outer jacket could be black for more formal occasions [16]. The court robe and *mǎng* robes (*mǎng páo* 蟒袍) for high princes should be *xīng huáng* 杏黃 “apricot yellow” (Fig. 9), those of lesser ones be *jīn huáng* 金黃 “golden yellow” (Fig. 10), while imperial family members of lower ranks were permitted to be *lán* 藍 blue and *shí qīng* 石青 “azurite blue” [12]. No one outside the imperial family could use any kind of yellow unless the privilege was expressly conferred.

Yellow is taken to symbolize fame, progress, and advancement. In the old Chinese calendar, lucky days are yellow (*huáng dào* (jì)rì 黃道(吉)日), which possibly stems from the Eternal Wheel of life in Buddhism [20].

In popular beliefs, yellow is associated with death. This probably stems from the correlation

of the color yellow with the element “soil.” The “Yellow Springs” (*huáng quán* 黃泉) is a term denoting the underworld. The expression “to return to the Yellow Springs” (*mìng guī huáng quán* 命歸黃泉) means “to meet one’s end.” In Daoism, yellow is the symbol of the deified Lǎo zǐ 老子 (the ancient philosopher of the Spring and Autumn 春秋 period (770–476 BCE) who was regarded by the Daoists as the founder of their school). In landscape painting and poetry, yellow is related to autumn and faded leaves and, by extension, to the end of the year and humans’ advanced age. It seems plausible that the association between dropping leaves with failure of a plan and disillusionment with life inspired the negative meaning of yellow in MSM, which is “failure to achieve something” [14].

Yellow also means “infant” and derives from the compound *huáng kǒu* 黃口 “yellow mouth,” which originally denoted “nestling” as the mouths of baby birds usually appear yellow [14]. On the Chinese stage, a yellow face is designated for devious and shrewd characters [21].

In imperial China, the term *huáng mén* 黃門 (lit. “yellow gate”) referred to eunuchs. In MSM, any form of the arts or literature which implicitly or explicitly touches upon the topic of sex or

nudity can be labeled as “yellow.” The compounds *dǎhuáng* 打黃 “to attack the yellow,” *sǎohuáng* 掃黃 “to wipe out the yellow” refer to the campaigns against pornography. On the other hand, a “yellow-blossom woman” (*huánghuānǚ* 黃花女) is one who is still a virgin.

NB: “yellow movie” means “pornographic movie,” whereas the famous telephone directory, the *Yellow Pages*, is not a “yellow book” in the Chinese sense.

Green and Blue

Qīng 青, one of the canonical colors, covered all shades from green and blue through dark-gray. The standard combinations include *qīngtiān* 青天 “[blue] sky” and *qīngcǎo* 青草 “[green] grass.” In MSM, there are separate, psychologically salient terms for green (*lǜ* 綠), blue (*lán* 藍), and gray (*huī* 灰). *Qīng* 青, however, continues to function as a color term with a context-dependent meaning [24].

“Rising straight up in a blue sky” (*qīng yún zhí shàng* 青雲直上) is a metaphor for a meteoric rise in one’s career. The “blue bird” *qīngniǎo* 青鳥 is a messenger from the mythical Queen Mother of the West; hence, any messenger. However, one should never wear light or dark blue flowers or ribbons in the hair: it is unlucky. Traditionally, blue eyes are regarded as ugly [3].

The word *lán* 藍, the basic color term for BLUE in MSM, derives from the name of the indigo plant, the phrase “Green-blue is obtained from the indigo plant, but is more green-blue than the indigo plant” *Qīng qǔ zhī yú lán ér qīng yú lán* 青取之於藍而青於藍 figuratively means “The student surpasses the master.”

Kuí-xīng 奎星, the god of literature, was originally a scholar, who was frustrated in his ambitions and committed suicide, is often represented with a blue face and wears green robes [3]. On the Chinese stage, blue face indicates an arrogant rascal [21].

The figurative meaning of *qīng* 青 is “not too far advanced in growth or life” or even “careless.” Thus “green years” *qīngnián* 青年 (“green” + “years”) means “youth,” *lèngtóuérqīng* 愣頭兒青 (“reckless” + “head” + “green”) refers to a quick-tempered person and *qīngpí* 青皮 (“green” + “peel”) stands for “an idle mischievous person.” Internet slang includes the terms like *qīngwā* 青蛙 “[green] frog” that refers to an ugly young person and 小青馬 *xiǎoqīngmǎ* “small green horse” that means “a young Marxist.”

Green dyes had always been most difficult for the Chinese artisans. Indeed, in former times green was a problem for dyers everywhere. In spite of the prevalence of this color in nature, it proved almost impossible to obtain a successful green dye. Only the berries from buckthorn, or certain other shrubs from the *Rhamnus* family, could produce one, but they could not be collected in any practical quantity. Therefore, the common practice was to dye threads blue with indigo and then use one of several yellow solutions made from various other plants. The result looked fine at first, but the yellow was usually fugitive and soon faded out leaving only the blue [16].

Green *lǜ* 綠 (etymologically “yellowish-green”) is one of the colors that life takes on and is the emblem of the spring. “Green clouds” *lǜyún* 綠雲 is an epithet for the hair of a beautiful girl.

Green was a color especially prized by Manchu women, who may have seen it as a symbol of growing things, hence expressing fertility; it was forbidden for men, except for the court eunuchs [16].

But green can also be a negative symbol. A man wearing a green turban (*lǜmàozi* 綠帽子, or *lǜtóujīn* 綠頭巾) is a cuckold and the “green mansion” (*qīnglóu* 青樓) is a brothel. In the last decade, the term “green tea bitch” (*lǜchábiāo* 綠茶婊) – formed by a metaphor for the innocent and charming appearance of a girl with long silky black hair and the formant that refers to her actual calculating and manipulative behavior – has become current in China.

The Chinese attach great importance to combinations of the two complementary colors, red and green. Painting may still be referred to as *dānqīng* 丹青 (“cinnabar-red” + “grue”) [3]. The expression “blue hills and green streams” (*qīng shān lǜ shuǐ* 青山綠水) that is a metaphor for charming natural landscape stems from the homophonous blue-and-green (*qīnglǜ* 青綠) landscape painting style. Azurite mineral blue and malachite mineral green were the principal colors used for portraying scenic elements [25]. The blue-and-green manner appears to have been specially chosen to illustrate themes of Daoist paradise, mountain retreats and imperial parks, eremitism, immortality, and alchemy [4].

To ensure a long life the Chinese have recourse to certain complicated charms, one of those is burial clothes, known as “longevity garments” (*shòuyī* 壽衣). Among these clothes, there is one robe in particular on which special pains have been lavished to imbue it with this priceless quality. It is a long silken gown of the deepest blue color, with the word “longevity” (*shòu* 壽) embroidered all over it in thread of gold. To present an aged parent with one of these costly and splendid mantles is esteemed by the Chinese an act of filial piety and a delicate mark of attention [26].

Purple

The color *zǐ* 紫 purple became sacral in Daoism: Daoist texts were referred to as “purple books” (*zǐ shū* 紫書), Laozi, according to the legend, was once accompanied by purple clouds when traveling. “Purple palace” (*zǐ gōng* 紫宮) is the term that indicates the celestial home of the supreme deity, which is believed to be the around the North Star. The Imperial Palace complex in Beijing (built in

1402–1420) is aligned with the North Star and is aimed to be the terrestrial projection of the celestial home of the supreme deity. This is the reason why its complete name is “Purple Forbidden City” (*Zǐjìnchéng* 紫禁城) [20].

During the Ming dynasty (1368–1644), purple was regarded as one of the imperial colors (together with reddish-black *xuán* 玄 and yellow *huáng* 黃) and was debarred from wearing amongst officials and common people [12]. The “purple paths” (*zǐ mò* 紫陌) are those that lead to the imperial capital, imperial edicts were referred to as “purple written admonitions” (*zǐ gào* 紫誥).

“Purple Maiden” (*Zǐgū* 紫姑) is the goddess of latrines in Chinese folk mythology. The placenta is known as the “carriage of the purple river” (*zǐhéché* 紫河車). On stage, heroes with purple faces can be recognized as loyal, imperturbable officials [3]. An extremely popular person can be described as “bright red and very purple” (*dàhóng dàzǐ* 大紅大紫).

Originally a textile term, *zǐ* 紫 covered the shades from purplish-red to purple in traditional China [22]. Nowadays, it mainly denotes violet.

Pink

Reddish-pink was originally designated by the term *hóng* 紅 and included in the RED category (see section “Red”). Since around the eleventh century, the literal meaning of the two Chinese characters that refer to the color pink is “powdered-red” (*fěnhóng* 粉紅) and “make-up red.” Characters meaning “peach-red” (*táohóng* 桃紅) are also sometimes used for “pink.” The color symbolizes female flightiness; it is also the color of fornication [3].

“Peach-blossom color” (*táosè* 桃色) figuratively means “illicit love” and is the result of loan translation from English *pink* which has the meaning “indecent, vulgar, romantic, or mildly ‘blue,’” as in *táosè xīnwén* 桃色新聞 (“pink news”) “scandalous news involving love affairs” [14].

The relatively recent term “Little Pink” (*xiǎofěnhóng* 小粉紅) that now broadly refers to young Chinese aggressive cyber-nationalists (of any gender) originally emerged on the popular women’s literature website Jinjiang Literature

City (Jinjiāng wénxué chéng 晉江文學城). Not only this online community had pink (*fěnhóng* 粉紅) as its background color, but also its content strategies deployed during the cross-strait memes war revealed that nationalistic discourses did feature an element of soft seduction, which may have been interpreted as “feminine” [27].

Conclusion

The human eye can distinguish myriads of hues, but the color vocabulary in a language is always limited. This happens because a color term is always an abstraction, and abstractions and generalizations do not remain intact at all stages, they *themselves* are the product of social and cultural development. Color in a language inspires associations and connotations that are often very subtle and determined by deep “culture memory.”

Synonyms

Color Contrast Sensitivity (rarely)

Definition

Chromatic contrast sensitivity is the ability to see chromatic contrast. Chromatic contrast refers to the occurrence of differences in *chromaticity* (saturated, hueful color) in a visual percept (scene, image, and stimulus). It may consist in differences across space (*spatial chromatic contrast*) or in changes of chromaticity across time

(*temporal chromatic contrast*). The term chromatic contrast is used in opposition to *achromatic contrast*, where differences only occur in *luminance* (greyscale). Chromatic contrast sensitivity depends on the spatial and temporal frequency of contrast (low-pass) in a way that differs from achromatic contrast sensitivity (band-pass).

Conceptual Clarifications

Almost every phenomenon in color vision involves contrasts between colors. Colors are not perceived absolutely, but relative to other colors, and contrasts between colors affect the appearance of the single colors (for review, see [1]). Nevertheless, the term *chromatic contrast* has been associated with certain aspects in the perception of color differences rather than others (for review see [2]). Conceptual connotations and distinctions in different contexts are clarified below.

Achromatic Contrast, Isochromaticity, and Isoluminance

Since human color vision involves an achromatic luminance dimension and two chromatic dimensions, visual contrasts may occur in terms of luminance or chromaticity. The term chromatic contrast must be understood as the complement of **achromatic contrast** [2]. Achromatic contrast refers to differences in luminance, which are perceived as lightness differences. Spatial achromatic contrasts may be illustrated by grey-scale images, such as black-and-white photos. Unlike achromatic contrast, chromatic contrast involves differences in chromaticity, which are differences along one or both of the chromatic dimensions as opposed to the achromatic dimension.

A chromatic stimulus may consist of purely achromatic contrasts, for example when the paper of a black-and-white photo yellowed over time, or when a grey-scale image was printed on color paper. Since such images only contain lightness differences they are void of chromatic contrast [3]. Such an image (or stimulus) is called **isochromatic** because it is constant (iso ~ equal) in chromaticity [4]. In contrast, an **isoluminant** image is constant in luminance and only varies in

chromaticities, implying that it has chromatic contrast while its achromatic contrast is zero.

Color Contrast

Because chromatic and achromatic differences are both part of human color perception, “color contrast” may appear to conceptually include both, achromatic and chromatic contrast. Nevertheless, color contrast is often used interchangeably with chromatic contrast in the literature depending on different research domains. The term **chromatic contrast** is mostly (but not exclusively) used in research on *contrast sensitivity* and its relationship to spatial and temporal frequency [2]. For this reason, the term chromatic contrast focuses on the distribution of color differences across space and time, and the ability of the observer to detect these differences (contrast sensitivity). On the other hand, the term **color contrast** is predominantly used in the context of research on *chromatic induction* that is the effect of color contrasts on *color appearance* (the subjective impression of color). In that context, *lightness contrast* is the greyscale complement of color contrast.

Color Edges, Spatial and Temporal Contrast

Chromatic (and achromatic) contrast may occur through variations across space or across time [2]. On the one hand, **spatial chromatic contrast** consists in the simultaneous occurrence of differences in chromaticity at different locations in space. On the other hand, **temporal chromatic contrast** refers to changes in chromaticity over time. In both cases the strength of the contrast is defined as the size of the difference in chromaticity.

The perception of contrast strongly depends on the transition between the two chromaticities. Transitions can be rather gradual or abrupt. For example, the chromatic difference between a raspberry and the surrounding leaves provides an abrupt transition between red and green, while the transitions between the colors of a rainbow are gradual. The temporal transition between the colors of a traffic light is abrupt, while the change of the chromaticity of sunlight during the day is very slow and gradual. Such transitions may be assessed by the spatial and temporal frequency of the color transition, respectively. The ability to

perceive chromatic contrast depends on these spatial [3] and temporal frequencies [5].

Chromatic edges (or *chromatic edge contrast*) are a particular kind of spatial chromatic contrast. Edge contrasts are related to the visual environment (*scenes*) because they are delimiting objects or other fundamental features of a scene such as shadows or highlights. As a result, while the term chromatic contrast focuses on the sensitivity to color contrasts in general, the notion of chromatic edges highlights the relationship between the beholder and their visual environment, and is rather used in the context of *scene statistics* (for review, see [1], e.g. [6, 7]).

Detection, Discrimination, and Contrast Sensitivity

Chromatic contrast sensitivity refers to the ability to see chromatic contrast. The term contrast sensitivity accounts for the dependence of sensitivity on the temporal and spatial distribution of contrasts. It is determined as the minimum contrast that an observer can see, given a specific temporal and spatial frequency. For this purpose, chromatic contrast sensitivity is measured with periodical changes in chromaticity, mostly involving two opponent chromaticities (see Fig. 1 and Method).

Chromatic sensitivity, color detection, and color discrimination involve chromatic contrast sensitivity; but they typically refer to differences in chromaticity independent of spatial or temporal frequency and are measured with single presentations of uniformly colored areas, typically colored disks (e.g. [8, 9]). **Chromatic sensitivity** is the general ability to see chromatic colors and is measured through color detection. **Color detection** consists in the discrimination of one color (*test*) from the neutral (i.e., *adapting*) background. Chromatic sensitivity is determined as the minimum difference in chromaticity between test color and background that can be detected. **Color discrimination** consists in the discrimination between two different colors (*test* and *comparison*) shown on the adapting background. The ability to discriminate colors (*sensitivity to color differences*) is determined through the minimum difference between the colors that can be discriminated on a given background. Color detection may be conceived as

Chromatic Contrast Sensitivity, Fig. 1 Typical Stimuli to Measure Spatial Contrast Sensitivity. From left to right: Gabor patches with achromatic contrast, L-M, S-(L + M), and all three contrasts combined. Note that the chromatic contrasts are more visible when looking from a closer

distance. This illustrates the low-pass frequency of the spatial chromatic contrast sensitivity function: Moving the observer toward the images makes the image larger and hence decreases spatial frequency

a special case of color discrimination, in which the test color is identical with the background.

Color detection and discrimination may be understood as special cases of chromatic contrast sensitivity. Chromatic contrast sensitivity converges to a maximum at low spatial and temporal frequencies and is zero above an upper boundary (*chromatic acuity*) of spatial frequencies (see Chromatic contrast sensitivity functions). By using sufficiently large color patches (> 1 degree visual angle) and presenting them for a sufficiently long time (> 200 ms) contrast sensitivity will be at maximum, independent of additional high spatial frequency (edges of stimuli) and high temporal frequency components (abrupt stimulus onset). In this way, color detection and discrimination performance reflects maximal chromatic contrast sensitivity in terms of spatial and temporal frequency, and does not require further specification of spatial and temporal frequency components in the stimulus (e.g. [8, 9]).

Spatial Resolution and Chromatic Acuity

Spatial resolution refers to the maximal spatial frequency that can still be seen, such as the minimum size of letters that can still be identified. Because of the tight relationship between spatial frequency and contrast sensitivity, contrast is also the complement of spatial resolution and acuity. For example, the smallest letters that can still be read when printed in black on a white paper, may not be identified when printed in light grey instead of black, because they have lower contrast than

the black letters. Hence, the spatial resolution depends on the contrast. This is also true for the spatial resolution of color vision. It can only be determined relative to a given contrast: The thinnest color line that may be detected with a high chromatic contrast, will be invisible with a lower contrast.

Visual acuity is a particular case of spatial resolution, which corresponds to the highest spatial frequency that can be detected at maximum contrast [2]. It can only be determined relative to a given contrast, such as between black letters and white background (cf. Snellen chart to measure visual acuity). Analogically, chromatic acuity corresponds to the highest spatial frequency that is still visible when presented with maximum chromatic contrast (e.g. [3]).

Method

Stimuli to measure chromatic contrast sensitivity vary periodically in chromaticity but are iso-luminant to separate achromatic from chromatic contrast (Fig. 1). To quantify chromatic contrast, differences between chromaticities need to be calculated.

Contrast Indices

Contrast indices calculate differences in chromaticities relative to a reference intensity, which is supposed to correspond to the adaptation of the

observer. Mainly three indices of contrast have been used.

The **Weber contrast** is calculated by the difference in intensity between two colors divided by the intensity of the background. This index is sensible if the background corresponds to the observer's adaptation color and the perception of the difference depends on the intensity of this background (e.g. [8, 9]).

Alternatively, the **Michelson contrast** divides the difference between intensities by the sum of their intensities. This approach is sensible when it may be assumed that observers are adapted to the intensities of the two colors, rather than to the background. Both indices are equivalent when the two colors vary symmetrically around the background. These two indices are useful for specifying contrast in sine-wave gratings, for example when measuring contrast sensitivity (e.g. [3, 10]).

Finally, the *Root Mean square* or **RMS contrast** consists in the standard deviation of the chromatic differences across a scene. In order to relativize these differences to the overall mean, the values are standardized before the calculation of the RMS index. This index may not only be used for contrast sensitivity measurements, but also for contrast distributions in scenes. However, still other indices to assess contrast are possible [2].

Color Differences

Color does not directly map to a physical measure (for review, see [1]). As with color in general, the quantification of chromatic contrast is relative to perception. Consequently, metrics of chromatic contrast are relative to the dimensions used to quantify chromaticity ("intensity of color"). For the measurement of contrast sensitivity, two ways to quantify chromatic contrast have been used.

First, contrast may be determined by the **physical** or *instrument contrast* [11]. The instrument contrast is the relative intensity of two chromatic lights (*component colors*), such as two monitor primaries or two monochromatic lights (e.g. [3]). The contrast between the two unmixed component colors corresponds to 100%, and they are mixed to produce intermediate levels of contrast (cf. Michelson contrast). The physical intensity of

each component color is typically measured as proportional luminance. However, the component colors, the dimension along which the difference is measured, and the scaling of the differences are arbitrary and depend on the device used to produce the colors.

Second, **cone-contrast** is used as a perceptual measure of contrast (for review, see [2], e.g. [12]). Cone contrasts are calculated by the difference in absorption (or excitation) of each of the three photoreceptors (L-, M- and S-cones) relative to the state of adaptation of that photoreceptor. Weber or Michelson contrast may be used for this purpose. Alternatively, colors may be directly represented in cone-contrast space, in which each of the three dimensions (ΔLMS) reflects the cone-contrast for one type of cone.

The most widespread approach is to determine contrast sensitivities relative to the **cone-opponent signal** of the postreceptoral, second-stage mechanisms (for review, see [2], e.g. [13, 14]). Chromatic contrast is then quantified in terms of the L-M and S-(L + M) cone contrast, such as in Fig. 1 (for review, see [15]). An advantage of this approach is that cone-opponent chromatic contrasts are orthogonal at isoluminance. The RMS contrast may be used to combine the contrasts across cone-types or opponent dimensions, such as in the rightmost panel of Fig. 1 (e.g. [12, 16]).

Note, that perceptual quantifications depend on the perceptual processes that are modeled by the difference metric and on the knowledge about these processes (for review, see [1]). Cone-contrasts relate chromatic contrast sensitivity to the low-level, cone-opponent processes of color vision. Hence, comparisons in contrast across different chromaticities are relative to these mechanisms. Higher-level, cortical mechanisms might involve different kinds or reweighed contrasts, and hence quantifications of contrast may differ for high-level mechanisms. In addition, studies may differ in how they define maximum cone-contrast, which affects the relative scaling of the cone-opponent axes.

Spatial Frequency

Gratings that alternate periodically between contrasting colors are used to control spatial

frequencies (Fig. 1). If stimuli consisted of simple uniform bars, sharp edges would occur between the single bars of the grating and between the grating and the background. Such sharp edges contain high spatial frequency components, which would be confounded with the low spatial frequency of the bars.

To avoid such edges between the bars, gratings are sinusoidally modulated [3, 10]. To further avoid sharp edges between grating and background contrasts are gradually reduced toward the edges through the application of a filter. As a result, the grating smoothly melts into the background and the strongest stimulation (i.e., contrast) is at the center of the grating. The molding of the overall grating through a filter is called an **envelope**, and in most cases this filter consists in a Gaussian function (*Gaussian envelope*). A sinusoidally modulated grating with an envelope is called a *Gabor patch* [17, 18]. Figure 1 provides examples of Gabor patches. Code for creating Gabor patches may be found in the PsychDemos of the Psychtoolbox [19].

While contrast may be controlled as the amplitude of the sinusoids, spatial frequency corresponds to the frequency of cycles. Since the perceived spatial frequency depends on the retinal image, it also depends on the distance of the eye to the grating (cf. Fig. 1). For this reason, spatial frequencies are quantified as *cycles per degree* (cpd) of visual angle. The visual angle accounts for the distance. At 0.5 cpd, one cycle covers 2 degrees, which is approximately the size of the fovea. Two degree visual angle roughly correspond to a width of 2cm at a distance of 57cm, or the size of a thumb at arm's length.

Note that there is a trade-off between controlling the number of cycles and the size of stimuli [3, 18]. Stimuli should be large enough to show a sufficient number of cycles for all frequencies (e.g. 2.5 cycles, cf. [2, 18]). For gratings above 3–4 cpd chromatic aberration produces luminance artifacts that influence detection thresholds. This is mainly the case for blue-yellow gratings, since the wavelength compositions for red and green chromaticities do not differ strongly, resulting in a similar refraction [3, 4].

Classical studies used absent-present judgments [3] or adjustment tasks [10] to measure chromatic contrast sensitivity, often with experienced observers. Instead, alternative forced choice tasks avoid relying on observer criteria. For example, gratings may be presented at different time points (e.g. [14]), at different locations of the display (e.g. [16]), or with different orientations (e.g. [13]), and observers indicate the time point, location or, respectively, the orientation of the grating through a forced-choice response.

Temporal Frequency

High temporal frequencies correspond to fast flicker between contrasting chromaticities, low frequencies to slow, and gradual transitions. Temporal frequency is quantified as cycles per second that is *Hertz* (Hz).

Temporal contrast sensitivity is measured through **heterochromatic flicker** [5]. In this setup, chromaticities periodically change, and temporal transitions are sinusoidally modulated to control specific temporal frequencies. At high frequencies, chromaticities are seen as an unchanging mixture of contrasting chromaticities (*flicker-fusion*). At extremely low frequencies, the change in chromaticity is not visible, either. For example, the slow change in chromaticity of daylight remains usually unnoticed in everyday life. Note that achromatic artifacts occur in L-M flicker due to latency differences between L- and M-cones [2].

Spatiotemporal contrast sensitivity, i.e., contrast sensitivity as a function of spatial and temporal frequency, may be measured by oscillating between gratings that are phase-shifted by 90 degree and hence show spatially inverse (green-red-green vs. red-green-red) contrasts [10].

Chromatic Contrast Sensitivity Functions

The relationship between contrast sensitivity and spatial and temporal frequency is captured through chromatic contrast sensitivity functions (cCSF). In CSFs, contrast sensitivity is represented along the y-axis as a function of spatial frequency (*spatial contrast sensitivity*

function, sCSF), or temporal frequency (*temporal contrast sensitivity function*, tCSF). All axes are usually scaled logarithmically.

Spatial Contrast Sensitivity

Chromatic spatial contrast sensitivity functions are **low-pass** [3, 4, 13]. This means that contrast sensitivity declines with high spatial frequencies (“narrower lines”), but barely changes when spatial frequency approaches zero, i.e., when the transition between contrasting colors is completely gradual. The chromatic sensitivity function reaches its maximum at about 0.5 cpd, i.e., when one cycle covers the whole fovea (see above). This low-pass pattern is largely independent of absolute luminance [16].

The low-pass pattern contrasts the one found for achromatic sCSFs. Achromatic sCSFs are band-pass with a peak at about 3–5 cpd and decreasing sensitivity toward both, higher and lower spatial frequencies. At the same time, acuity is much higher for achromatic (cut-off at 40–60 cpd) than for L-M (about 12 cpd) and S-(L + M) contrasts (10 cpd). In fact, due to chromatic aberration the effective resolution is only 3–4 cpd for the S-(L + M) contrast [2]. Moreover, increasing eccentricity from the fovea toward the periphery has a stronger attenuating effect on L-M contrast sensitivity than on achromatic contrast sensitivity, while S-(L + M) contrast sensitivity declines with eccentricity in a similar way as achromatic contrast sensitivity [2, 14].

These properties of spatial contrast sensitivity imply that “very thin” stripes are still visible when shown in black and white, but “disappear” when shown as isoluminant colors [3, 16]. This has been used, for example, in image compression (e.g., TV broadcast) where high-spatial frequency information is saved in achromatic contrast only and chromatic high-spatial frequency information is discarded [20]. However, chromatic contrast sensitivity is overall higher than achromatic contrast sensitivity when expressed as cone-contrasts instead of physical contrasts [12].

Temporal Contrast Sensitivity Function

Temporal frequency modulates chromatic contrast sensitivity in a similar way as spatial frequency [2, 5]. It is mainly **low-pass**, with only a slight attenuation in sensitivity below about 1 cpd.

It is highest when colors change 1–3 times per second (1–3 Hz), and temporal resolution is at about 30–40 Hz. In contrast, achromatic contrast sensitivity peaks between 5 and 20 Hz, and has a higher cut-off value for temporal resolution (~50 Hz). Since both, spatial and temporal cCSFs are low-pass, the spatiotemporal cCSF is also low-pass [10].

Due to the lower temporal resolution for differences in chromaticity, heterochromatic flicker can be used to exactly determine isoluminance for an individual observer (**heterochromatic flicker photometry**). At a temporal frequency of 15–20 Hz chromaticities of contrasting colors fuse, and the only flicker left is achromatic. The brightness of one of the contrasting colors is adjusted until there is no flicker, which implies that the luminance of the two colors is equal [21].

Development

As with adults, the spatial (L-M) CSF is low-pass in infancy (8–30 weeks), and develops through a steady increase in overall sensitivity and in spatial resolution [22]. In contrast, temporal (L-M) CSFs are band-pass in 3 month old infants, and develop an adult-like low-pass profile only at the age of 4 months [11]. Across the life-span, chromatic contrast sensitivity increases steadily until adolescence, and decreases thereafter [23].

Eye Movements

While sensitivity for luminance contrast decreases during *smooth pursuit*, sensitivity for isoluminant L-M and S-(L + M) contrast increases (10–16%), starting about 50 ms before eye movement [24]. An increase in contrast sensitivity has also been found during *optokinetic nystagmus*, but not *vestibulo-ocular reflex* ([25], for review, see [26]).

Theories on Chromatic Contrast Sensitivity

Physiological Basis

The optics of the eye blur the retinal image and explain a major part of sensitivity loss for high spatial frequencies for both, chromatic and achromatic contrasts. Blurring through chromatic aberration further reduces S-(L + M) contrasts of high

spatial frequency in the retinal image. In addition, the distribution of cones across the retina (*cone mosaic*) modulates contrast sensitivity. The scarcity of S-cones in the retina further attenuates the spatial resolution of S-(L + M) contrast sensitivity [4].

Chromatic contrasts are processed by two independent **pathways** that go from the *retinal ganglion cells* via the *lateral geniculate nucleus* (LGN) to the *visual cortex*. The *parvocellular* pathway processes L-M, the *koniocellular* pathway S-(L + M) contrasts. The decrease in contrast sensitivity with eccentricity agrees with the distribution of parvocellular and koniocellular receptive fields across the retina [2, 14]. Moreover, the increase of chromatic contrast sensitivity during pursuit and optokinetic nystagmus indicates a boost of the parvo- and koniocellular system [24, 26].

Functional Role in Ecology

Chromatic contrasts are statistically independent from luminance contrast in natural scenes, and hence provide an additional source of information for object identification apart from luminance contrast [6, 7]. Furthermore, spatial L-M contrast sensitivity is optimal for the detection of red and yellow fruits at reaching distance (for review, see [1, 27]).

Chromophore

Malgorzata Szymczyk

Wilson College of Textiles, North Carolina State University, Raleigh, NC, USA

Definition

The term chromophore was introduced by Otto N. Witt in 1876, as a combination of ancient Greek terms *chromo* (color) and *phore* (bearer) [1]. In the field of color science, chromophore refers to the structural unit in an organic molecule that is responsible for color. In other words, chromophores enable organic molecules to absorb light in the visible region (400–700 nm) of the electromagnetic spectrum.

Basis for Color in Organic Compounds

Unlike most organic compounds, dyes possess color because they absorb light in the visible spectrum, have at least one chromophore, and have a conjugated system. When any one of these features is lacking from the molecular structure, color does not exist [2].

Absorption of Visible Light

When visible light strikes a colored object, certain wavelengths of that light are absorbed, and the remaining wavelengths are reflected and can be detected by the human eye. The colors associated with the absorbed and observed light are shown in Table 1. The colors absorbed and observed at a given wavelength are known as complementary colors. Combining the two colors produces white light again.

Prior to the development of synthetic colorants, color verses molecular structure in organic compounds was illustrated through conjugated olefins (see Table 2). As the length of the conjugated system increased, the absorption intensified and the maximum absorption wavelength lengthened. Here, a comparison of the colors of 1,3,5-heptatriene (colorless), Vitamin A (yellow), and

β -Carotene (orange) illustrate the importance of extended conjugation in this chromophoric system. It is also clear that many conjugated double bonds must be assembled in order to produce a deep color such as blue. As the next section will show, the development and use of chromophores more readily led to a variety of deep colors even with fewer conjugated double bonds.

Chromophore, Table 1 Wavelengths of absorbed and reflected colors

Wavelength absorbed (nm)	Color absorbed	Color reflected (observed)
400–435	Violet	Yellow–green
435–480	Blue	Yellow
480–490	Green–blue	Orange
490–500	Blue–green	Red
500–560	Green	Purple
560–580	Yellow–green	Violet
580–595	Yellow	Blue
595–605	Orange	Green–blue
605–700	Red	Blue–green

Chromophores and Conjugation in Organic Colorants

Examples of well-known chromophores in color chemistry are shown in Fig. 1, which include simple (nitro, azo, and methine) and more complex (anthraquinone and triarylmethane) systems. About 70% of synthetic dyes have the azo chromophore, with anthraquinone dyes comprising about 15% [3]. As illustrated in Fig. 2, chromophores are effective when incorporated into a conjugated system – a series of alternating single and double bonds [2, 3]. In the present example, the azo group gives color when placed between two phenyl groups but not when placed between methyl groups. In commercial dyes, the azo chromophore is produced by combining a coupler such as 2-naphthol (**1**) and a diazonium compound (**2**), as shown in Fig. 3. The formation of azo dyes such as **3** illustrates that the azo chromophore ($-\text{N}=\text{N}-$) often exists in combination with the corresponding hydrazo ($=\text{N}-\text{NH}-$) form (e.g., **4**). The two forms give overlapping absorption bands in the visible spectrum, with the hydrazo form producing the band at higher wavelength.

The azo chromophore affords a full scope of colors (yellow–black) and can vary in number in a given dye structure, as illustrated through textile

Chromophore, Table 2 Influence of conjugated double bonds on color in organic compounds

Poly(olefin) compounds	Number of conjugated –C=C– bonds	Color
 1,3,5-Heptatriene	3	Colorless
 Retinol (vitamin A)	5	Light yellow
 β -Carotene	11	Orange
 Decapreno- β -carotene-d10	15	Dark blue
 Dodecapreno- β -carotene	19	Black

dyes C. I. Disperse Yellow 3, C. I. Reactive Green 19, C. I. Acid Brown 75, and C. I. Direct Black 22 (Fig. 4). These four examples also show that azo dyes are used in a variety of dye application classes, providing colorants having affinity for all major fiber types.

The anthraquinone chromophore gives mostly yellow–green dyes (e.g., Fig. 5), with a few examples of brown and black anthraquinones found among the vat dyes for cotton. Generally, the anthraquinone chromophore gives brighter colors and better photostability than the azo chromophore, especially among the red, blue, and green

Chromophore, Fig. 4 Examples of commercial yellow–black dyes containing one to four azo groups

dyes. Like azo dyes, anthraquinone dyes cross many application classes, giving colorants for all major textile fiber types. Because of their brightness, anthraquinone-based products are complementary to azo dyes, which can be rather dull. They are more expensive than azo colorants, however. While atypical, dyes having an azo and an anthraquinone chromophore exist. They enable the formation of mixed colors by combining, for

example, an anthraquinone blue system with an azo yellow system (see C. I. Reactive Green 6).

The triarylmethane chromophore gives mainly red–green dyes (e.g., Fig. 6). Triarylmethane dyes are distinguished for their bright colors and high color strength but they typically have poor photostability. The chromophoric system consists of a central carbon atom joined to three aromatic rings, generally with electron-donating groups in the

para-position. Unlike azo and anthraquinone chromophores, the triarylmethane chromophore is not used with textile coloration in view. The more common targets are inks, cosmetics, and biological stains.

The combination of chromophores and conjugated groups produces colored systems referred to as chromogens [4]. Examples of chromogens in a pair of commercial dyes are given in Fig. 7. Figure 7 also shows that commercial dyes contain groups known as auxochromes – color aiders. These groups can influence color [1, 4] and other dye properties (e.g., solubility, fiber affinity) and comprise electron-donating groups such as amino and hydroxyl groups and electron-withdrawing groups such as nitro, carboxylic acid, and sulfonic acid groups.

Synonyms

Color stereoscopic effect; Color stereoscopy;
Depth in color

Definition

Chromostereopsis refers to a phenomenon of binocular stereopsis that depends on binocular disparity due to the difference in color [1–4]. For example, red and blue on the same surface can appear to lie in different depth planes.

Overview

When the background is black (Fig. 1), the majority of observers see red objects closer to them than blue ones (red-in-front-of-blue observers), while a minority of observers see the reversal (blue-in-front-of-red observers) and the rest do not experience the phenomenon. On the other hand, when the background is white (Fig. 2), the perceived

Chromostereopsis, Fig. 1 Chromostereopsis. For the majority of observers, the *inset* made up of *red* random dots appears to be in front of the surround consisting of *blue* ones. For a minority, the *inset* appears to be behind the surround. The rest do not experience the phenomenon. Chromostereopsis is strong when observers see the image at a distance

Chromostereopsis, Fig. 2 When the background is *white*, the effect is reversed and it is weaker than when the background is *black*. Those who see *red* in front of *blue* in Fig. 1 see *blue* in front in this image, while those who see *blue* in front of *red* in Fig. 1 see *red* in front in this image

depth order is reversed, and the effect is weaker than when the background is black.

Goethe [5] may deserve to be the first person who proposed the notion of advancing color (red) versus receding color (blue), but he did not notice the binocular aspect of chromostereopsis. According to Thompson et al.'s review [6], the history of chromostereopsis goes back at least to the work of Donders in 1864 [7], while Vos' review [4] suggested that Donders first reported this effect in 1868, followed by Bruecke [8] in the same year. According to Dengler and Nitschke's review [9], however, Brewster [10] reported in 1851 that owing to the chromatic aberration of the lens, short-wavelength colors are seen stereoscopically as more distant.

Both Donders and Bruecke attributed chromostereopsis to accommodative feeling, which was translated to the perception of distance [4]. Blue or short-wavelength light has a larger refractive index than the red or long-wavelength one. This makes the color rays run in a different way as shown in Fig. 3. This is called "longitudinal chromatic aberration" [3]. This idea suggests that red should be closer than blue even if both colors are placed in the same depth plane because a closer object comes into focus at the posterior part. Moreover, this idea suggests that chromostereopsis should be seen monocularly. Yet, these two suggestions are not the cases, and this idea is not regarded as a plausible explanation of chromostereopsis [3, 11].

It was Bruecke [8] in 1868 who found the binocular nature of the phenomenon [4]. The optical axis of an eyeball is slightly (about 5° = angle gamma or angle alpha) shifted in the outward direction from the visual axis. Red light is thus projected to a more temporal part of the retina than does blue light (Fig. 4) because of the difference in refractive index of both colors. This physiological optics is called "transverse chromatic aberration" [3]. This idea suggests that red should be perceived in front of blue through binocular stereopsis based upon the binocular disparities of both colors. More specifically, a closer object projects to a more temporal part in the retina and so does red light. This suggestion, however, made

Chromostereopsis,

Fig. 3 The longitudinal chromatic aberration. *Blue* has the focus nearer to the lens than *red* because of the difference in the refractive index depending on color

Chromostereopsis, Fig. 4 The transverse chromatic aberration. *Red* light is projected to a more temporal part of the retina than does *blue* light because of the difference in the refractive index depending on color. Note that the optical axes are slightly (about 5°) diverged from the visual axes

Appearance: *blue* in front

Appearance: *red* in front

Chromostereopsis, Fig. 5 Einthoven's covering method. *Blue* in front of *red* is generated or enhanced by covering the temporal parts of both pupils (*upper image*), while *red* in front of *blue* is produced or enhanced by covering the nasal parts of both pupils (*lower image*)

Bruecke immediately reject his hypothesis because some of his observers reported red receding with respect to blue.

According to Vos [4], Einthoven discovered in 1885 that chromostereopsis is enhanced or reversed by using a simple method as shown in Fig. 5 [11, 12]. Covering the temporal parts of both pupils forces observers to see blue in front of red (upper image of Fig. 5). On the other hand, covering the nasal parts of both pupils makes observers see red in front of blue (lower image of Fig. 5). This method was also demonstrated by Kishto [13]. He cited Kohler's article [14] in

1962, which did not mention any other literature, though.

Subsequently, Einthoven's covering method was simplified to the method using artificial pupils. Nasally placed artificial pupils gave blue in front of red (upper image of Fig. 6), while temporally placed ones rendered red in front of blue (lower image of Fig. 6) [15–23]. Vos [4, 16, 18] attributed chromostereopsis to interactions between each individual pupil decentralization (angle gamma) and the Stiles-Crawford effect. The Stiles-Crawford effect is a phenomenon that the rays entering the eye through the peripheral

Chromostereopsis, Fig. 6 When artificial pupils are placed nasally, observers see *blue* in front of *red*. On the other hand, when artificial pupils are placed temporally, observers see *red* in front of *blue*

Chromostereopsis, Fig. 7 The center-of-gravity model. This model takes longitudinal chromatic aberration into account, in which the perceived position of a color is judged to be at the center of gravity of its diffused light

regions of the pupil are less efficient than those through the central region [24]. This two-factor model, which Vos [4] called the “generalized Bruecke-Einhoven explanation,” has been widely accepted, while a few authors did not approve it [25].

Many studies suggested that pupil size affects chromostereopsis [19, 21–23], which supports the generalized Bruecke-Einhoven explanation. Simonet and Campbell [26], however, did not find any consistent relationship between pupil size and chromostereopsis.

Einhoven’s original finding was explained by the center-of-gravity model (Fig. 7) [27]. It is

hypothesized that the position of color is determined at the center of gravity in the range of each projected light onto the retina. For example, when the temporal half is occluded, the center of gravity of red light shifts in the relatively nasal direction, while that of blue light deviates in the temporal direction (upper image of Fig. 7). These shifts give binocular disparities to produce the blue-in-front-of-red stereopsis. When the nasal half is occluded, the center of gravity of red light shifts in the relatively temporal direction, while that of blue light deviates in the nasal direction (lower image of Fig. 7). These shifts give binocular

Chromostereopsis, Fig. 8 Images suggested by Hartridge [32]. *Red-in-front-of-blue* observers see the *black inset* in front of the *white* surround in the *left*

image, and they see the *inset* behind the surround in the *right image*. *Blue-in-front-of-red* observers see the reversal. Observe these images at a distance

disparities to produce the red-in-front-of-blue stereopsis.

In 1965, Kishto reported a tendency that red appears to be in front of blue at high levels of illumination, while blue appears to be in front of red at low levels of illumination, i.e., 17 of 25 observers (68 %) reported so [13]. This finding was influential and drew much attention [3], though it was questioned by some studies [9, 26]. For example, Simonet and Campbell [26] reported a reversal in the direction of the chromostereopsis for 16 of 30 observers (53%) when the ambient illumination was increased, but six of them (38%) reported a change toward the blue-in-front-of-red chromostereopsis. Moreover, at low illuminance, there was lack of correlation between the direction of chromostereopsis and transverse chromatic aberration, which may indicate that there may be a supplementary binocular factor in chromostereopsis [26].

In 1928, Verhoeff reported that the perceived depth order between red and blue is reversed by changing the background from black to white (Fig. 2) [9, 28–30]. One account is that red surrounded by white lacks blue, while blue surrounded by white lacks red, suggesting that there are virtually blue and red edges, respectively [28]. According to Faubert [31], Hartridge described in his 1950s textbook [32] that “when both black and white pattern lie on a uniformly

Chromostereopsis, Fig. 9 Chromostereopsis when the background is not achromatic. Luminance of *red* is highest, followed by *green* in this image. Those who see *red* in front of *blue* in Fig. 1 see the *inset* in front of the surround; those who see *blue* in front of *red* in Fig. 1 see the *inset* behind the surround. Observe this image at a distance. Einthoven’s covering method (Fig. 5) also works

coloured background a stereoscopic effect is frequently noticed” (Fig. 8).

With respect to this luminance-dependent reversal, Faubert [31, 33] proposed a new demonstration of chromostereopsis in which colors are bordered with each other (Fig. 9) and pointed out

Chromostereopsis, Fig. 10 Faubert’s luminance-profile-based idea [31]. Color fringes or luminance profiles of a *red* object in front of *green* such as that in Fig. 9 produced by transverse chromatic aberration are depicted. It is supposed that mirror images are rendered to each eye. This binocular disparity generates a special type of binocular stereopsis which depends on luminance contrast polarity of the object’s edges [34, 35]. This stereogram

demonstrates *red-in-front-of-green* appearance when cross-fusers use the *left* and *middle* panels or uncross-fusers see the *middle* and *right* ones. The perceived depth is determined by the luminance profiles shown in the *lower row*. Note that *red* or *light-gray* rectangles do not give binocular disparity with respect to the frames; both fringes of each rectangle promote to make binocular stereopsis

Chromostereopsis, Fig. 11 If the luminance order of the two colors in Fig. 10 is exchanged, the apparent depth is reversed. This stereogram demonstrates *red-behind-green* appearance when cross-fusers use the *left* and *middle* panels or uncross-fusers see the *middle* and *right* ones

the critical role of luminance profiles caused by transverse chromatic aberration in subsequent binocular stereopsis. The luminance-profile-dependent binocular stereopsis is thought to correspond to the one which Gregory and Heard showed in 1983 as shown in Fig. 10 [34, 35], though Faubert did not mention it. If the luminance order is reversed between the two colors, the apparent depth is reversed as shown in Fig. 11. When two colors are isoluminant, two depth planes are simultaneously observed (rivaldepth) with luster where two colors meet (Fig. 12) [31]. In addition, actually a century ago, Einthoven [11] had pointed out the role of luminance profiles caused by transverse chromatic aberration, but

he had assumed the perception of convex or concave objects depending on where illuminated light comes from and made a monocular explanation like the crater illusion (Fig. 13).

Faubert's luminance-profile-based model [31, 33] can be extended to explain the luminance-dependent reversal (Fig. 14). Suppose that white consists of red, green, and blue. Given transverse chromatic aberration when the background is black, and suppose that red appears to shift in one direction, blue appears to shift in the opposite direction (upper panel of Fig. 14), and green does not change the apparent position. Then, when the background is white, red appears to slightly shift in the opposite direction, with

Chromostereopsis, Fig. 12 Isoluminant colors make observers perceive rivaldepth with luster. Note that precise isoluminance is realized depending on displays and individuals

Chromostereopsis,

Fig. 13 Idea of the crater illusion. The central *square* appears to be in front of the background in the *upper left panel*, while that appears to be behind the background in the *upper right panel*. This depth effect depends on the positions of highlighted or shadowed edges [36]. The basic idea of Einthoven [11] is demonstrated in the *lower panels*

Chromostereopsis, Fig. 14 Faubert’s model can be extended to explain the color reversal. If *red* and *blue* objects are vertically aligned with the *black* background but appear to be shifted in position by transverse chromatic aberration as shown in the *upper panel*, the expected shifts with the *white* background are reversed as shown in the

lower panel. This idea accounts for the luminance-dependent reversal (Fig. 2). Note that this stereogram demonstrates *red-in-front-of-blue* appearance when cross-fusers use the *left* and *middle* panels or uncross-fusers see the *middle* and *right* ones

Chromostereopsis,

Fig. 15 If transverse chromatic aberration moves *red* to the *left* and *blue* to the *right* (uppermost row) and does not change the position of *green*, *red* surrounded by *white* appears to shift rightward (middle row), while *blue* surrounded by *white* appears to shift leftward (lowermost row). Thus, apparent position shifts of the two colors are reversed depending on whether the background is *black* or *white*. Note that the *left* column shows the physical position of the two colors, and the *right* column demonstrates apparent positions of the two colors with color fringes produced by color mixture of shifted component colors

yellow leading to and magenta (color mixture of red and blue) following red. On the other hand, blue appears to slightly shift in the same direction as that of red when the background is black, with cyan (color mixture of blue and green) leading to and magenta following blue (lower panel of Fig. 14). Figure 15 shows the pictorial explanation of how transverse chromatic aberration induces the positional shifts of colors.

It was reported that the effect of chromostereopsis is large when observers see the image at a distance [13, 27, 31], whether observers are of the red-in-front-of-blue type or the blue-in-front-of-red type [27]. This issue remains open. In addition, there is no literature to suggest any involvement of myopia or hyperopia in chromostereopsis.

The majority of observers see red in front of blue with the black background in a light environment. How many people see blue in front of red? In Luckiesh [15], 11% (1 of 9 observers) did

Chromostereopsis, Fig. 16 The *inset* appears to be in front of the surround. High-luminance and/or high-contrast objects appear to be closer than low-luminance and/or low-contrast ones

Chromostereopsis, Fig. 17 Images showing a tendency that the *inset* appears to be behind the surround

so. The proportion was 4% (1 of 25 observers) in Kishto [13], 30% (9 of 30 observers) in Simonet and Campbell [26], 7% or 14% (1 or 2 of 14 observers) in Dengler and Nitschke [9], 20% (4 of 20 observers) in Kitaoka et al. [27], and 21% (16 of 75 observers) in Kitaoka [37].

Color anomaly people also see chromostereopsis. Kishto [13] examined three color anomaly observers, one being a strong protanope, one being a mild deutanope, and the third having too poor color discrimination to read any of Ishihara plates. They all saw red in front of blue with the black background in a light environment.

It is thought that some part of the effect is due to luminance differences or contrast differences

(Fig. 16), with bright objects appearing closer than dim ones [6] or high-contrast objects appearing closer than low-contrast ones [38]. Saturation also affects chromostereopsis [11, 13]. Desaturation decreased the depth effect, though desaturation is inevitably accompanied by changes in luminance, contrast, or spectrum.

Moreover, if an image consists of the inset and surround, there seems to be a tendency that the inset appears to be behind the surround (Fig. 17). This phenomenon seems to be observed with achromatic images, too (Fig. 18).

Neural correlates of chromostereopsis were investigated using visually evoked potentials [39]. Results demonstrate that the depth illusion

Chromostereopsis, Fig. 18 Achromatic images also show the tendency that the *inset* appears to be behind the surround

obtained from contrast of color implicates similar cortical areas as classic binocular depth perception.

Summary

It is summarized that chromostereopsis is a phenomenon of binocular stereopsis based upon binocular disparity produced by some interaction between optic properties of color rays and further neural processing. Chromostereopsis is a ubiquitous phenomenon and has a considerable pile of observations gained in its long research history.

János Schanda: Deceased.

CIE 1931 standard colorimetric observer	Ideal observer whose color-matching properties correspond to the CIE color-matching functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ adopted by the CIE in 1931
CIE 1964 standard colorimetric observer	Ideal observer whose color-matching properties correspond to the CIE color-matching functions $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, $\bar{z}_{10}(\lambda)$ adopted by the CIE in 1964

the additive mixture of the three matching primary stimuli (it is practical to use monochromatic red, green, and blue primary lights, see later) is projected onto the other side of the field. By using adjustable light attenuators, the light flux of the three matching stimuli is adjusted to obtain a color appearance match between the two fields. When this situation is reached, the test stimulus can be characterized by the three luminance values of the matching stimuli reaching the eye of the observer. This is described by the following equation:

$$[C] \equiv R[R] + G[G] + B[B] \quad (1)$$

where $[C]$ is the test stimulus; $[R]$, $[G]$, and $[B]$ are the unit values of the three matching stimuli; and R , G , and B are the amount taken from $[R]$, $[G]$, and $[B]$ to match the stimulus $[C]$. The $\equiv$ sign means “matches” (for more details, see [2]). Invariably, one of the primary stimuli has to be added to the test stimulus to complete the match.

If one uses monochromatic test stimuli of equal power, wavelength to wavelength along the visible spectrum (theoretically between 360 nm and 830 nm, practically between 380 nm and 780 nm), and matches these monochromatic radiations with the three selected matching stimuli (in different wavelength regions, one of the matching stimuli has to be added to the test stimulus to get a color match, and in that case the matching stimulus is shown in Eq. 1 as it would be subtracted from the other two matching stimuli), one can build up the color-matching functions.

Using $1 \text{ cd} \cdot \text{m}^{-2}$ monochromatic red light of 700 nm as $[R]$, $4.5907 \text{ cd} \cdot \text{m}^{-2}$ monochromatic green light of 546.1 nm as $[G]$ and $0.0601 \text{ cd} \cdot \text{m}^{-2}$ monochromatic blue light of 435.8 nm as $[B]$ for the units of the matching stimuli, one gets for unit power of monochromatic lights of the spectrum curves as shown in Fig. 1 called color-matching functions (CMFs) and usually written in the following form: $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, $\bar{b}(\lambda)$.

Visual experiments have shown that color stimuli are additive, i.e., if the test stimulus is composed of two sub-stimuli $[C(\lambda_1)]$ and $[C(\lambda_2)]$ of different wavelengths, the amounts of the $[R]$, $[G]$, and $[B]$ matching stimuli, also called *primaries*, that are used to match $[C(\lambda_1)]$ and

Overview

Colors with different spectral compositions can look alike (i.e., be metameric). An important function of colorimetry is to determine which spectral compositions appear metameric. The use of visual colorimeters for this purpose is handicapped by variations in the color matches made among observers classified as having normal color vision, so that different observers make different matches. Visual colorimetry also tends to be time-consuming. For these reasons, it has long been the practice in colorimetry to make use of sets of mean or standard color-matching functions to calculate tristimulus values for colors: Equality of tristimulus values for a pair of colors indicates that the color appearances of the two colors should match, when viewed under the same conditions by an observer for whom the color-matching functions apply. The use of standard sets of color-matching functions makes the comparison of tristimulus values obtained at different times and locations possible [1]. *The standard colorimetric observers are defined by their color-matching functions.*

According to Grassman’s laws, a *test color stimulus* can be matched by the additive mixture of three properly selected *matching primary stimuli* (properly selected includes independence; i.e., none of the primary stimuli can be matched by the additive mixture of the other two). The test stimulus is projected on one side of a bipartite field;

**CIE 1931 and 1964
Standard Colorimetric
Observers: History, Data,
and Recent Assessments,
Fig. 1** Color-matching
functions of the CIE 1931
RGB system

$[C(\lambda_2)]$ have to be added to match the additive mixture of the two test stimuli $[C_1 + {}_2]$. This can be expanded to a spectrum that has different spectral radiance values at different wavelength: the color of the compound spectrum $S(\lambda)$ can be described by three tristimulus values:

$$\begin{aligned} R &= \int_{380\text{nm}}^{780\text{nm}} \bar{r}(\lambda) S(\lambda) d\lambda, \\ G &= \int_{380\text{nm}}^{780\text{nm}} \bar{g}(\lambda) S(\lambda) d\lambda, \\ B &= \int_{380\text{nm}}^{780\text{nm}} \bar{b}(\lambda) S(\lambda) d\lambda \end{aligned} \quad (2)$$

In many applications, it is inconvenient to use negative lobes of the $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, $\bar{b}(\lambda)$ functions; therefore, the CIE decided in 1931 to transform the $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, $\bar{b}(\lambda)$ functions using a matrix transformation to imaginary CMFs (non-real in the sense that they cannot be physically realized). The transformed CMFs are the $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ functions, and the tristimulus values determined using these functions are the X , Y , and Z tristimulus values. Their calculation is similar at those of the R , G , and B values shown in Eq. 2.

The transformation matrix has the following form:

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} 2.768 & 892 & 1.751 & 748 & 1.130 & 160 \\ 1.000 & 000 & 4.590 & 700 & 0.060 & 100 \\ 0 & 0.056 & 508 & 5.594 & 292 \end{bmatrix} \cdot \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (3)$$

The original color-matching experiments were conducted with small, approximately 2° diameter homogeneous color patches, seen foveally. The central part of the fovea is covered by a yellow pigmentation, the yellow spot or macula lutea. If larger-colored fields are viewed or slightly off-axis objects are viewed, the above CMFs do not hold anymore, as the yellow pigmentation absorbs light in a part of the visible spectrum.

In 1964 CIE standardized CMFs for a 10° visual field, the so-called large field CMFs. Based on similar direct visual investigations performed mainly by Stiles and Burch [3] with contributions by Speranskaya [4], these functions are now used in many applications. To distinguish between values determined using the 2° or the 10° functions, the latter are distinguished by the subscript “10,” and thus the 10° observer’s CMFs are termed $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, $\bar{z}_{10}(\lambda)$ (Fig. 2).

Regarding the use of the tristimulus values and further colorimetric calculations, see chapters on “CIE chromaticity co-ordinates,” “CIE chromaticity diagram,” “CIE illuminants,” and “CIELAB” and other chapters on advanced colorimetry.

Short History of the CIE Colorimetric Observer

CIE colorimetry is based on the tristimulus theory developed by the greatest scientists of the nineteenth century, including Thomas Young, Helmholtz, and Maxwell (see [5]). Maxwell's demonstrations and ideas, in particular, lead to the specification of the trichromatic theory; he showed, e.g., the three color mixture curves of the spectrum and plotted the spectrum locus in the color triangle.

Photometry and colorimetry were further developed in the USA that lead to the so-called OSA excitation curves.

During the second decade of the twentieth century, two groups in the UK performed detailed investigations of color matching: John Guild at the NPL and David Wright at the Imperial College, London. The two researchers used different primaries, and it was a great surprise that after their transformation into a common system, they matched reasonably well.

During those years the CIE formulated the wish to develop a colorimetric description of colored glasses used for traffic control. At the 1931 meetings of the CIE, the USA and UK groups discussed in detail the pros and cons of different systems and finally agreed that a mean of the Guild and Wright data should be adopted, but transformed to a system with nonnegative

CMFs. These were the $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ CMFs that we still use today.

One major problem with the CIE 1931 XYZ system is that the values of the primaries were determined photometrically, so that the $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ functions had to be reconstructed using $V(\lambda)$ function, the visibility function (now called spectral luminous efficiency for photopic vision). As it turned out later, the $V(\lambda)$ dataset is in error in the blue part of the spectrum, and this error has been transferred to the color-matching functions.

Experiments carried out in the 1950s at NPL by Stiles and Burch led to a new set of 10-deg CMFs; this time the primaries and test lights were radiometrically calibrated, so they were not contaminated by photometric errors. As mentioned in the Overview, the NPL data were harmonized with data measured by Speranskaya, and these were standardized as the CIE 10° observer in 1964.

Recently, the fundamental experimental data have been reanalyzed, together with new cone spectral sensitivity measurements made in red-green dichromats and blue-cone monochromats of known genotype to produce new cone spectral sensitivity curves of the three cone receptors (the cones are mainly responsible for daylight vision and color perception) as well as transformations to $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ -like curves [6, 7]; see Chapter on CIE Physiologically-Based Colour-Matching Functions and Chromaticity Diagrams. The cone fundamentals are known as the

CAT

Definition

According to the CIE International Lighting vocabulary [1], chromatic adaptation is a visual process whereby approximate compensation is made for changes in the colors of stimuli, especially in the case of changes in illuminants. The effect can be predicted by a chromatic adaptation transform (CAT) which is used to predict the corresponding colors, a pair of color stimuli that have same color appearance when one is seen under one illuminant and the other is seen under the other illuminant.

Overview

CAT is used for many industrial applications. For example, it is highly desired to produce color constant merchandise, i.e., products do not change color appearance across different illuminants. A color inconstancy index named CMCCON02 was proposed by the Colour Measurement Committee (CMC) of the Society of Dyers and colorists (SDC) [2]. CAT is a key element in the color inconstancy index. It later became the ISO standard for textile applications [3]. Furthermore, chromatic adaptation is the most important function included in a color appearance model, which is capable of predicting color appearance under different viewing conditions such as illuminants, levels of luminance, background colors, media (e.g., reflection,

transmissive, and self-luminous display). The CIE [4] recommended CIECAM02 for the application of the color management systems. For illumination engineering, a CAT is also required for predicting the color rendering properties between a test and a reference illuminant [5].

Various chromatic adaptation transforms have been derived to fit a particular experimental dataset (see later). The workflow for a typical CAT is given in Fig. 1 including three steps.

Step 1 Cone response transform

To model the physiological mechanisms of chromatic adaptation, one must express stimuli in terms of cone responses, denoted R , G , and B or L , M , and S , suggestive of long-wave (red), middle-wave (green), and short-wave (blue) sensitivities, respectively. This is achieved by using a linear transform via a 3 by 3 matrix. Various transform functions have been proposed having different fundamental primaries.

Step 2 Chromatic adaptation mechanism

This step transforms cone responses of the test sample, (R, G, B) , under the test illuminant, defined by (R_w, G_w, B_w) , into the adapted cone responses (R_c, G_c, B_c) under the reference illuminant, defined by (R_{rw}, G_{rw}, B_{rw}) . The transforms are different between different CATs.

Step 3 Reverse cone transformation

Using the reverse cone transform (an inverse matrix of Step 1) to calculate the corresponding cone responses, (R_c, G_c, B_c) in Step 2), back to tristimulus values under the reference illuminant.

CIE TC1-52 technical report entitled *A Review of Chromatic Adaptation Transformations* [6] gave a comprehensive survey of the transforms, and reported the testing results of the state of the art CATs using large accumulation of experimental datasets.

Four of them, the most well-known, are introduced below. The notation used in each CAT is different from those used in its original version, but agree with those given in Fig. 1.

von Kries Chromatic Adaptation Transform

The earlier CAT was that developed by von Kries in 1902. He studied chromatic adaptation

CIE Chromatic Adaptation: Comparison of von Kries, CIELAB, CMCCAT97, and CAT02,

Fig. 1 The three steps included in a chromatic adaptation transform

following the Young-Helmholtz theory, which assumes that, although the responses of the three cone types (R , G , B) are affected differently by chromatic adaptation, the relative spectral sensitivities of each of the three cone mechanisms remain unchanged. Hence, chromatic adaptation can be considered as a change of sensitivity by a constant factor for each of the three cone mechanisms. The magnitude of each factor depends upon the color of the stimulus to which the observer is adapted. The relationship, given in Eq. 1, is known as the *von Kries coefficient law*.

$$\begin{aligned} R_c &= \alpha R \\ G_c &= \beta G \\ B_c &= \gamma B \end{aligned} \quad (1)$$

where R_c , G_c , B_c and R , G , B are the cone responses to give the same appearance under the

reference and test illuminants respectively. The α , β , and γ are the von Kries coefficients corresponding to the change in sensitivity of the three cone mechanisms due to chromatic adaptation. These are calculated using Eq. 2.

$$\alpha = \left(\frac{R_{rw}}{R_w} \right); \quad \beta = \left(\frac{G_{rw}}{G_w} \right); \quad \gamma = \left(\frac{B_{rw}}{B_w} \right) \quad (2)$$

where

$$\frac{R}{R_w} = \frac{R_c}{R_{rw}}; \quad \frac{G}{G_w} = \frac{G_c}{G_{rw}}; \quad \frac{B}{B_w} = \frac{B_c}{B_{rw}}$$

and R_{rw} , G_{rw} , B_{rw} and R_w , G_w , B_w are the cone responses for the reference white under the reference and test illuminants, respectively.

In 1974, the CIE technical committee on color rendering [5] adopted a version of the von Kries model derived by Helson et al. [7]. It is still in use for making small adjustments to account for

differences in illuminants to be compared for color rendering properties. This procedure is given below.

Step 1 Calculate the R , G , B , R_{rw} , G_{rw} , B_{rw} , and R_w , G_w , B_w using Judd's cone transformation in Eq. 3.

$$\begin{bmatrix} R \\ G \\ B \end{bmatrix} = \begin{bmatrix} 0,000 & 1,000 & 0,000 \\ -0,460 & 1,360 & 0,100 \\ 0,000 & 0,000 & 1,000 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (3)$$

Step 2 Calculate the α , β , and γ von Kries coefficients and the R_c , G_c , B_c values using Eqs. 1 and 2.

Step 3 Calculate the X_c , Y_c , Z_c using Eq. 4.

$$\begin{bmatrix} X_c \\ Y_c \\ Z_c \end{bmatrix} = \begin{bmatrix} 2,954 & -2,174 & 0,220 \\ 1,000 & 0,000 & 0,000 \\ 0,000 & 0,000 & 1,000 \end{bmatrix} \begin{bmatrix} R_c \\ G_c \\ B_c \end{bmatrix} \quad (4)$$

CIELAB

Although the CIELAB color space [8] was recommended by CIE in 1976 solely for quantifying color differences under daylight illuminants, it can also be used with other illuminants because it includes a von Kries type of transformation, i.e., by dividing the tristimulus values (X , Y , Z) of the sample by those (X_w , Y_w , Z_w) of illuminant, respectively. The assumption made is that L^* , a^* , and b^* values will be the same for a pair of color constant colors under a test and a reference illuminant.

CMCCAT97 Chromatic Adaptation Transformation

Lam and Rigg [9] investigated the degree of color appearance change for object colors between the test and reference illuminants. They conducted a memory matching experiment using 58 textile samples under illuminants D65 and A. A transformation was derived to fit the experimental data. The transform was named BFD transform, which

is similar to the structure of Bartleson's. At a later stage, this transform was enhanced by Luo and Hunt [10] to become CMCCAT97. It was also included in the first version of CIE color appearance model, CIECAM97s [11]. CMCCAT97 transform is given below.

A parameter, L_a (adapting luminance), is required for calculating a parameter, D , which allows for the degree of chromatic adaptation taking place. L_a is calculated as $L_w Y_b / 100$ where L_w is the luminance in cd/m^2 of the reference white under test illuminant and Y_b is the luminance factor of the background. The whites are normally the perfect reflecting diffuser, in which case $Y_w = Y_{rw} = 100$. Other whites may be used but, to avoid ambiguity, their details should be recorded.

Step 1 Calculation of R , G , B , R_{rw} , G_{rw} , B_{rw} and R_w , G_w , B_w using Eq. 5.

$$\begin{bmatrix} R \\ G \\ B \end{bmatrix} = M \begin{bmatrix} X/Y \\ Y/Y \\ Z/Y \end{bmatrix}$$

where

$$M = \begin{bmatrix} 0.8951 & 0.2664 & -0.1614 \\ -0.7502 & 1.7135 & 0.0367 \\ 0.0389 & -0.0685 & 1.0296 \end{bmatrix} \quad (5)$$

Step 2 Calculation of degree of adaptation (D) using Eq. 6.

$$D = F - \frac{F}{1 + 2L_a^{1/4} + L_a^2/300} \quad (6)$$

where $F = 1$ for surface samples seen under typical viewing conditions.

D is set to one by assuming that the color of the illuminant is usually discounted during visual color-inconstancy assessments for object colors. This is proposed by CMCCON97 [12].

Step 3 Calculation of the corresponding RGB cone responses using Eq. 7.

$$\begin{aligned} R_C &= [D(R_{wr}/R_w) + 1 - D]R \\ G_C &= [D(G_{wr}/G_w) + 1 - D]G \\ B_C &= [D(B_{wr}/B_w^p) + 1 - D]|B|^p \end{aligned} \quad (7)$$

(when B is negative, B_c must be made negative)

$$\text{where } p = (B_w/B_{wr})^{0.0834}$$

Step 4 Calculation of the corresponding tristimulus values using Eq. 8.

$$\begin{bmatrix} X_c \\ Y_c \\ Z_c \end{bmatrix} = M^{-1} \begin{bmatrix} R_c Y \\ G_c Y \\ B_c Y \end{bmatrix} \quad (8)$$

CAT02 Transform

Various tries were carried out to test the performance of different transformations by CIE TC1-52 *Chromatic Adaptation Transformation*. At the same period, CIE TC 8-01 *Color Appearance Models for Color Management Applications* was aimed to improve the CIECAM97s model and in some degree to simplify the model. This resulted in CIECAM02 [4] which includes CAT02. At a later stage, CMC also modified its original CMCCON97 color constancy index [12] to CMCCON02 [2] by replacing CMCCAT97 by CAT02. The CAT02 is given below:

Step 1 Calculation of $R, G, B, R_{rw}, G_{rw}, B_{rw}$ and R_w, G_w, B_w using Eq. 9.

$$\begin{bmatrix} R \\ G \\ B \end{bmatrix} = M_{CAT02} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (9)$$

where

$$M_{CAT02} = \begin{bmatrix} 0.7328 & 0.4296 & -0.1624 \\ -0.7036 & 1.6975 & 0.0061 \\ 0.0030 & 0.0136 & 0.9834 \end{bmatrix}$$

Step 2 Calculation of degree of adaptation (D) using Eq. 10.

$$D = F \left[1 - \left(\frac{1}{3.6} \right) e^{\left(\frac{L_a - 42}{92} \right)} \right] \quad (10)$$

where F is set to 1.0, 0.9 or 0.8 for “average,” “dim,” or “dark” surround condition, respectively and L_a is the luminance of the adapting field. In theory D should range from 0 for no adaptation to the adopted white point to 1 for complete adaptation to the adopted white point. In practice the minimum D value will not be less than 0.65 for a “dark” surround and will exponentially converge to 1 for “average” surrounds. If D from Eq. 10 is larger than one, D should be set to one. For predicting color inconstancy of a sample using CMCCON02, D value should be set to one assuming a complete adaptation.

Step 3 Calculation of R_c, G_c, B_c from R, G, B (similarly R_{wc}, G_{wc}, B_{wc} from R_w, G_w, B_w)

$$\begin{aligned} R_c &= [D(R_{rw}/R_w) + 1 - D]R \\ G_c &= [D(G_{rw}/G_w) + 1 - D]G \\ B_c &= [D(B_{rw}/B_w) + 1 - D]B \end{aligned} \quad (11)$$

Step 4 Calculation of the corresponding tristimulus values using equation 12.

$$\begin{bmatrix} X_c \\ Y_c \\ Z_c \end{bmatrix} = M_{CAT02}^{-1} \begin{bmatrix} R_c \\ G_c \\ B_c \end{bmatrix} \quad (12)$$

Experimental Datasets Investigated by CIE TC1-52

CIE TC1-52 members also collected large number of datasets. These were accumulated using mainly three different psychophysical methods [13]: Haploscopic matching, memory matching, and magnitude estimation. The former is to ask observers to perform color matching between two viewing fields say one eye views a stimulus under illuminant A and the other eye views another stimulus under illuminant D65. Memory matching is to ask observers to describe color stimuli using a particular color order system such as Munsell under one illuminant with full adaptation. Prior the experiment, the observers

need to be trained to learn the perceptual attributes such as Munsell Value, Chroma, and Hue. Magnitude estimation is to ask observers to estimate color stimuli in terms of lightness, colorfulness, and hue. Table 1 shows the datasets chosen to be extensively studied by CIE TC1-52.

Evaluation of CATs

The four CATs introduced earlier were tested using the datasets given in Table 1 from eight sources. In total, 568 corresponding-color pairs were gathered. The results are summarized in Table 2 in terms of mean CMC(1:1) Δ*E* units [22].

It was found [17] that the typical observer variation for studying chromatic adaptation was about four CMC (1:1) units. Hence, if a CAT has an error of prediction equal to or less than four units, it may be considered to be satisfactory. As shown in Table 2, the most accurate transform for each dataset (the underlined and bold value) is usually less than four units except for Luo et al. (WF) data set. The ten data sets are divided into two groups: reflection and non-reflection samples. The Braun and Fairchild, and Breneman data sets are included in the latter group. (Braun and Fairchild data were obtained by comparing between CRT and reflection printed colors, and Breneman

data were based on projected transmissive colors.) The weighted mean for each CAT was calculated to represent the performance for each group or overall. The weighted mean was used to take into account the number of corresponding pairs in each data set.

The results showed that for both data groups, CMCCAT97 and CAT02 outperformed von Kries and CIELAB with a big margin, and the former and the latter two gave similar degree of error of prediction. This implies that the former two and the latter two CATs gave very similar results. This implies that von Kries law alone is insufficient to develop a reliable CAT. The matrix in Step 1 of Fig. 1 is essential for a reliable CAT.

Also, CMCCAT07 was derived by fitting only one dataset, the Lam and Rigg. It also predicts well to the other datasets. This implies that all corresponding datasets agree reasonably well with each other. CAT02 can be considered as an improvement of CMCCAT97 because it is simpler and was developed by fitting all the datasets in Table 2.

Another method to evaluate the performance of CATs is to visualize the color shifts in a color space. The predicted shifts for the four CATs in Table 2 and the corresponding experimental shifts from all data were plotted in CIELAB *a***b** diagram. The Helson et al. dataset [7] was used to illustrate the transformations to CIE C from A illuminant as shown in Fig. 2. This dataset was chosen because it has been the most widely used and the earlier produced dataset. In Fig. 2, the point where the two vectors cross, and the unmarked end represent experimental results viewed under illuminants A and C, respectively. The “+” symbol represents the predicted chromaticity from one particular transformation. The distance between each corresponding “+” and unmarked end indicates the error of prediction except for CIELAB. For a good agreement between experimental results and a particular transformation, the two vectors should overlap. For perfect agreement between CIELAB and the experimental results, each vector in Fig. 2a Reference source not found. should have a zero length (or a single point). As can be seen in Fig. 2, such perfect agreement was not found. However, there is a clear pattern of color shift in each figure. That

Note: The bold and underlined italic values indicate the best transform for each data set

is, the color shift increases for more colorful colors as C_{ab}^* increases.

Note that experimental errors would be expected to be random. When a diagram shows a consistent pattern in the errors of prediction of a particular color region, this is most likely to be due to a fault in the transform. See the example the von Kries diagram at very colorful regions.

Figs. 2a–d show that there are large differences between the four different CATs in terms of predictive color shifts. For the von Kries transform (Fig. 2b), the predictive shifts only move along the a^* direction, i.e., red-green shift. Both von Kries and CIELAB gave reasonable predictions for the low chroma colors, but large predictive errors for high chroma colors. CMCCAT97 (Fig. 2c) gave a quite precise prediction for almost all colors with some exceptions in the colorful yellow and blue regions. The prediction of those regions were improved for CAT02 transform (Fig. 2d). It can also be seen that in general, the magnitudes and shifts for CAT02 are very similar to those of CMCCAT97 (see Fig. 2c). This indicates that although CMCCAT97 was derived to fit only the Lam and Rigg dataset, it gave almost the same performance as that CAT02 (see Table 2). This

implies that there is a great similarity between different datasets

Further Extension to CAT16

The CATs, especially CAT02, have been applied successfully in various applications. However, some shortcomings have been identified for some very saturated colors (close to the spectrum locus of the chromaticity diagram) [23]. These colors result in negative tristimulus values, meaning out of the limit of chromaticity diagram. Although they are rare in real applications, efforts have been made to correct them. In 2016, Li et al. [24] published CAM16, CAT16, and CAM16-UCS by modifying CIECAM02, CAT02, and CAM02-UCS, respectively. The main effort was to overcome the shortcoming by replacing M_{CAT02} in Eq. (9) by M_{16} matrix in Eq. (13) in CAT02.

$$M_{16} = \begin{pmatrix} 0.401288 & 0.650173 & -0.051461 \\ -0.250268 & 1.204414 & 0.045854 \\ -0.002079 & 0.048952 & 0.953127 \end{pmatrix} \quad (13)$$

CIE Chromatic Adaptation: Comparison of von Kries, CIELAB, CMCCAT97, and CAT02, Fig. 2 Graphical presentation of corresponding a^*b^* values showing direction and magnitude of the experimental visual results under CIE standard illuminant A and C, plotted between the point

where the two vectors cross and the unmarked end, and between the former point and the predicted shifts plotted using an “+” symbol, whereas (a) von Kries, (b) CIELAB, (c) CMCCAT97, and (d) CAT02

The difference between CAT16 and CAT02 is the latter to include negative lobes in the cone response functions, and the functions are narrower, and the latter to have all positive cone response functions with all positive energy across the visible spectrum. The two CATs gave exactly the same performance in CIELAB color difference to predict all corresponding datasets. It is envisaged that CAM16 and CAT16 will be

adopted by CIE to become CIECAM16 and CIECAT16 respectively in the near future.

CIE Chromaticity Coordinates (xyY)

Stephen Westland
Colour Science and Technology, University of
Leeds, Leeds, UK

Definition

Chromaticity coordinates x , y , and z are calculated from CIE tristimulus values X , Y , and Z thus:

$$\begin{aligned}x &= X/(X + Y + Z), \\y &= Y/(X + Y + Z), \\z &= Z/(X + Y + Z).\end{aligned}\tag{1}$$

If the chromaticity coordinates and one of the tristimulus values (e.g., Y) are known, then it is possible to compute tristimulus values thus:

$$\begin{aligned}X &= xY/y, \\Z &= zY/y = (1 - x - y)Y/y.\end{aligned}\tag{2}$$

Chromaticity Coordinates

The use of chromaticity coordinates is an alternative, and often more useful, representation to the use of tristimulus values. The tristimulus values X , Y , and Z of a stimulus are the amounts of three primary lights that on average an observer would use to match the stimulus and as such form a specification of the stimulus. If the Y tristimulus value is calculated on an absolute basis, then it represents the luminance of the color stimulus, in candelas per square meter, for example [1]. When relative tristimulus values are calculated so that $Y = 100$ for a similarly illuminated and viewed perfect Lambertian reflector, then the Y of a stimulus is equal to its reflectance factor or, in some cases, transmittance factor. It is customary to regard Y as the luminance factor of the stimulus, and this is an approximate correlate of the perceptual attribute of lightness [1].

The CIE system of colorimetry was designed so that the Y tristimulus value correlates, at least approximately, with lightness. To achieve this and other objectives, the primaries upon which the CIE system is based are usually referred to as being *imaginary* and certainly cannot be physically realized. This means that the X and Z tristimulus values do not correlate, even approximately, with any perceptual attributes, and this is a motivation for calculating other attributes that can provide such correlates. The chromaticity coordinates (see Eq. 1) are a type of relative tristimulus values. So, for example, if $X = 20$, $Y = 40$, and $Z = 20$ for a stimulus, then $x = 20/80 = 0.25$ and $y = 40/80 = 0.5$. This indicates that the stimulus is 25% of X , 50% of Y , and 25% of Z , of course.

Inherent in the way that the chromaticity coordinates are calculated (Eq. 1) is the constraint that $x + y + z = 1$, and this means that there are only really two degrees of freedom since $z = 1 - x - y$. Since there are only two *free* variables, it is possible to construct a 2D diagram referred to as a chromaticity diagram. By convention, in the chromaticity diagram (which forms a sort of map of colors), x and y are plotted on the abscissa and ordinate, respectively (Fig. 1).

Properties of the Chromaticity Diagram

Figure 1 shows an illustration of a chromaticity diagram though note that the colors are purely representative and are not meant to accurately denote the color at any point in the diagram. The original color-matching experiments carried out by Wright and Guild that formed the basis of the CIE system of color specification in 1931 used real, but different, red (R), green (G), and blue (B) lights as the primaries but were transformed into a common set of monochromatic primaries; the R was at 700 nm, the G at 546.1 nm, and the B at 435.8 nm. The color-matching functions are the amounts of each of these primaries used on average by a group of observers to match each wavelength of light in the visible spectrum (380–780 nm). The vertices of the triangle in Fig. 1 are at the chromaticities of the CIE RGB primaries.

If two lights are represented in the chromaticity diagram by two points, then chromaticities of the additive mixtures of the two lights will be represented by the straight line that joins the two points. Thus, in Fig. 1, all mixtures of the R and G primaries would lie on the straight line joining the chromaticities of the R and G primaries. The range of colors that can be matched by a set of primaries is sometimes referred to as the gamut; the gamut of a dichromatic system (based on just two primaries) is very small and impractical for most purposes. When there are three primaries (a trichromatic system), then the gamut becomes a triangle in the CIE chromaticity diagram such as the RGB triangle illustrated in Fig. 1.

The curved horseshoe-shaped locus of the chromaticity diagram is defined by the chromaticities of the monochromatic wavelengths of light. Since all real color stimuli are combinations of the monochromatic wavelengths, and given the earlier observation about how color mixtures are defined in the chromaticity diagram, it is clear that the gamut of all physically realizable colors is the convex hull constrained by the curved spectral locus. Similarly, it is also clear that no matter how carefully three primaries are selected (and no matter whether they are monochromatic or not),

CIE Chromaticity Coordinates (xyY),

Fig. 1 CIE 1931 chromaticity diagram showing the equal-energy stimulus (white circle) and the CIE RGB gamut (triangle denoted by R, G, and B)

the gamut (represented by a triangle in the chromaticity diagram) will always be a subset of the gamut of all physically realizable colors. Thus, if the gamut of the CIE RGB primaries is considered (see Fig. 1), it is evident that much of the spectral locus cannot be matched by additive mixture of the primaries. The 1931 CIE system was defined by transforming the color-matching functions from the RGB primaries into a system of imaginary primaries XYZ where the whole spectrum (from 380 to 780 nm) could be matched by all-positive amounts of the three primaries. The XYZ primaries are referred to as imaginary because they cannot be realized physically; in Fig. 1, the outer triangle – defined by the x,y chromaticities (0,0), (1,0), and (0,1) – is the gamut of the XYZ primaries, and it is evident that the gamut of physically realizable colors lies within this.

The largest gamut that can be achieved by any RGB system would be obtained by using primaries whose chromaticities were close to, or on, the spectral locus at the approximate wavelengths 400, 520, and 700 nm, but this would still leave parts of the gamut of physically realizable colors outside of the RGB triangle (see Fig. 2). A further consideration is that a practical RGB system consists of chromaticity and luminance.

Consequently, an RGB display device based on monochromatic primaries would likely not be very bright. For many purposes, it is important to be aware that gamuts are three dimensional [2].

Primaries that consist of light at more than one wavelength are less saturated than monochromatic lights of a similar hue; however, they also tend to be much brighter. The design of modern display devices involves many such considerations, but many use primaries that correspond closely to the sRGB trichromatic standard whose gamut is represented in Fig. 2 [3]. It is evident that the sRGB gamut (in 2D chromaticity space at least) covers less than half of the gamut of physically realizable colors. However, the fact that reflectance spectra for objects in the world tend to vary smoothly with wavelength [4] has the consequence: the practical gamut of real-world colors is much smaller than the horseshoe-shaped locus would suggest. Monochromatic stimuli, for example, are incredibly rare in the natural or man-made world.

The chromaticity diagram is perceptually non-uniform [1]. This was visually demonstrated by the MacAdam ellipses which showed the chromaticities of stimuli that were just noticeably different from a standard color. Around each standard

CIE Chromaticity Coordinates (xyY),

Fig. 2 CIE chromaticity diagram showing the gamut of a hypothetical monochromatic RGB primary system (*larger triangle*) and the sRGB standard primary system (*smaller triangle*)

color, the locus of the just discriminable colors was the ellipses whose size and orientation varied greatly throughout the chromaticity diagram. In a perceptually uniform space, these loci would be circles of identical size. Even lines of constant hue are curved in chromaticity space rather than being straight. The Abney effect, first observed in 1909, is a phenomenon such that there is a hue shift when white light is added to a monochromatic light [5]. The locus of the mixture of a white light (see the equal-energy stimulus in Fig. 1) and a monochromatic light would be a straight line in the chromaticity diagram. Problems with the lack of perceptual uniformity of the chromaticity diagram were part of the reason why non-linear transforms of the XYZ system were explored ultimately resulting in the CIE (1976) $L^*a^*b^*$ color space or CIELAB.

Further Considerations and Future Directions

Currently, there are two CIE xy chromaticity spaces corresponding to the 1931 (2° of visual angle) and 1964 (10° of visual angle) standard

observers, respectively. Work is underway to explore the possibility of a CIE standard observer that would include a visual angle parameter to allow a family of related chromaticity diagrams.

CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength

János Schanda
Veszprém, Hungary

Definitions

Chromaticity Diagram

Plane diagram in which points specified by chromaticity coordinates represent the chromaticities of color stimuli [1]

Note: In the CIE standard colorimetric systems, y is normally plotted as ordinate and x as abscissa, to obtain an x, y chromaticity diagram.

Purity (of a Color Stimulus)

Measure of the proportions of the amounts of the monochromatic stimulus and of the specified achromatic stimulus that, when additively mixed, match the color stimulus considered.

Note 1: In the case of purple stimuli, the monochromatic stimulus is replaced by a stimulus whose chromaticity is represented by a point on the purple boundary.

Note 2: The proportions can be measured in various ways.

Excitation Purity [p_e]

Quantity defined by the ratio NC/ND of two collinear distances on the chromaticity diagram of the CIE 1931 or 1964 standard colorimetric systems, the first distance being that between the point C representing the color stimulus considered and the point N representing the specified achromatic stimulus and the second distance being that between the point N and the point D on the spectrum locus at the dominant wavelength of the color stimulus considered, leading to the following expressions:

$$p_e = \frac{y - y_n}{y_d - y_n}$$

or

$$p_e = \frac{x - x_n}{x_d - x_n}$$

where (x, y) , (x_n, y_n) , (x_d, y_d) are the x, y chromaticity coordinates of the points C, N, and D, respectively.

Unit: 1

Note 1: In the case of purple stimuli, see Note 1 to “purity.”

Note 2: The formulae in x and y are equivalent, but greater precision is given by the formula which has the greater value in the numerator.

Note 3: Excitation purity, p_e , is related to colorimetric purity, p_c , by the equation:

$$p_e = \frac{p_c y}{y_d}$$

Colorimetric Purity [p_c]

Quantity defined by the relation

$$p_c = \frac{L_d}{L_n + L_d}$$

where L_d and L_n are the respective luminances of the monochromatic stimulus and of the specified achromatic stimulus that match the color stimulus considered in an additive mixture.

Note 1: In the case of purple stimuli, see Note 1 to “purity.”

Note 2: In the CIE 1931 standard colorimetric system, colorimetric purity, p_c , is related to excitation purity, p_e , by the equation $p_c = p_e y_d / y$ where y_d and y are the y chromaticity coordinates, respectively, of the monochromatic stimulus and the color stimulus considered.

Note 3: In the CIE 1964 standard colorimetric system, a measure, $p_{c,10}$, is defined by the relation given in Note 2, but using $p_{e,10}$, $y_{d,10}$, and y_{10} instead of p_e , y_d , and y , respectively.

Dominant Wavelength (of a Color Stimulus)
[λ_d]

Wavelength of the monochromatic stimulus that, when additively mixed in suitable proportions with the specified achromatic stimulus, matches the color stimulus considered in the CIE 1931 x, y chromaticity diagram.

Unit: nm

Note: In the case of purple stimuli, the dominant wavelength is replaced by the complementary wavelength.

Overview

x, y Chromaticity Diagram

Both in the CIE 1931 standard colorimetric system and the CIE 1964 standard colorimetric system, chromaticity coordinates are expressed as the ratio of the given tristimulus value and the sum of all three tristimulus values [2]:

$$x = \frac{X}{X + Y + Z}, \quad y = \frac{Y}{X + Y + Z}. \quad (1)$$

As the color-matching functions are the tristimulus values of the monochromatic stimuli, the chromaticity coordinates of the monochromatic stimuli can be calculated according to Eq. 1. In the plane rectangular x - y diagram the line of the chromaticity of the monochromatic stimuli bounds, together with the straight line connecting the red and blue endpoints of the spectrum, the area of visible stimuli [3]; see Fig. 1. The diagram produced by plotting x as abscissa and y as ordinate is called the CIE 1931 chromaticity diagram or the CIE (x, y) diagram. A similar chromaticity diagram can be constructed using the x_{10}, y_{10} chromaticity coordinates of the CIE 1964 standard colorimetric system.

The chromaticity diagram is often depicted in color; see Fig. 3 (in the section for dominant wavelength and purity). One has to emphasize, however, that in this figure, the colors are only for orientation. As shown in Fig. 1, if, e.g., on the computer the colors are mixed from the R, G, B primaries (the gamut of real RGB primaries of monitors is even smaller), the mixed colors have

CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength, Fig. 1 CIE 1931 chromaticity diagram, location of the equi-energy spectrum (E), the R, G, B primaries of the CIE 1931 system, and some wavelength along the spectrum loci are shown

to be inside the RGB triangle. On the boundary of the monochromatic stimuli, the emission spectrum reaching our eyes should contain only one single wavelength [4].

As seen in Fig. 3, the mid-part of the chromaticity diagram looks whitish. This is even more pronounced if a light source of that chromaticity illuminates a scene; a white paper will – under these conditions – look white, and this is caused by chromatic adaptation.

Chromaticity diagrams can be built also for the CIE 1976 u' , v' coordinates [5]. The 1976 u' , v' uniform chromaticity scale diagram (UCS diagram) is a projective transformation of the CIE 1931 x , y chromaticity diagram yielding perceptually more uniform color spacing, i.e., the perceived chromaticity differences are represented by more uniform coordinate differences. The transformation between the two systems is

$$\begin{aligned} u' &= \frac{4x}{-2x + 12y + 3} \\ v' &= \frac{9y}{-2x + 12y + 3} \end{aligned} \quad (2)$$

With these coordinates, the chromaticity diagram has the form as shown in Fig. 2. Comparing this diagram with the x , y diagram, it becomes

obvious how nonuniform the x , y diagram is (see details in entry ► “CIE u' , v' Uniform Chromaticity Scale Diagram and CIELUV Color Space”).

An equivalent transformation starting from the tristimulus values is

$$\begin{aligned} u' &= \frac{4X}{X + 15Y + 3Z} \\ v' &= \frac{9Y}{X + 15Y + 3Z} \end{aligned} \quad (3)$$

To be exact Euclidean distances in his diagram can be used to represent approximately the relative perceived magnitude of color differences between color stimuli of negligibly different luminances, of approximately the same size, and viewed in identical surroundings, by an observer photopically adapted to a field with the chromaticity of CIE standard illuminant D65 [6].

Dominant Wavelength and Purity

A color can be characterized by its tristimulus values or its chromaticity and the luminance (if it is a self-luminous object) or luminance factor (if it is a reflecting or transmitting object illuminated by a (standard) light source). It is difficult to visualize the chromaticity from the x , y values; an easier

CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength,
Fig. 2 CIE u' , v' chromaticity diagram

CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength, Fig. 3 A colored chromaticity diagram, where the basic components of excitation purity are shown

identification is by two other quantities: dominant wavelength and excitation purity.

Dominant and Complementary Wavelength

In Fig. 3, we see two colored samples (represented in the chromaticity diagram by A and B); they are illuminated by a source of neutral chromaticity (N). If a line is drawn from point N through point A or B, one reaches at the boundaries of the chromaticity diagram, at the spectrum locus points D and C, respectively. Points D and A are located on the same side of point N; thus, chromaticity of A is less saturated as that of D but has similar hue; therefore, the wavelength of the monochromatic radiation at point D is called the *dominant wavelength* (in our example 495 nm). By mixing radiation of the monochromatic radiation D and the neutral radiation N, one can create the chromaticity A.

For point B, as it is located on the far side of points N and C, one can produce the chromaticity N by mixing chromaticity B with C. Therefore, the wavelength of the spectral line at C is called the *complementary wavelength* for chromaticity B.

Excitation Purity

The relative distance of A (resp. B) from N, compared to the distances $\overline{DN}$ (resp. $\overline{B'N}$), is called *excitation purity* and describes how strongly the monochromatic stimulus is diluted by the radiation of N. For purple colors (in the triangle of points N-V-R), the monochromatic stimulus is replaced, as seen, by the stimulus on the purple boundary. In practice it is not necessary to calculate with the vector length, it is enough to take either the x or the y coordinates. One should take always those coordinates that are larger; thus, e.g., for the two chromaticity points A and B, the excitation purities are calculated as

Excitation purity of chromaticity point A :

$$p_{e,A} = \frac{x_A - x_N}{x_D - x_N} \quad (4)$$

Excitation purity of chromaticity point B :

$$p_{e,B} = \frac{y_B - y_N}{y_{B'} - y_N} \quad (5)$$

Colorimetric Purity

As mentioned under Definitions, another purity quantity, *colorimetric purity*, is defined by the luminance of the respective stimuli: Given the stimulus A, to mix this color from stimuli D and N, one needs luminance L_D and L_N . With these quantities, the colorimetric purity is

$$p_c = \frac{L_D}{L_N + L_D}. \quad (6)$$

Summary

With some practice, one gets a reasonable feeling of the chromaticity of monochromatic stimuli if their wavelength is given; thus, if the dominant/complementary wavelength of a stimulus is stated, one can form a mental picture of the stimulus. Similarly the excitation purity is also a relatively easily visualized quantity – how whitish the given colored stimulus is – thus, these two quantities are often used instead of the chromaticity coordinates for a quick description of the chromaticity of a stimulus. One has to emphasize – however – that the chromaticity of the neutral stimulus is important. In many colorimetric calculations, the CIE standard illuminant D65 is used as a reference neutral stimulus, but in some applications, the equienergetic stimulus is found.

The CIE 1931 x, y chromaticity diagram is the most often used diagram. It is, however, non-equidistant, i.e., in different parts of the chromaticity diagram, perceived equal chromaticity differences are observed as different coordinate differences. The CIE 1976 u', v' diagram is more equidistant and is generally used in lighting engineering.

There is one exception, the determination of correlated color temperature, which is determined in the CIE 1960 diagram, the coordinates of which are the following:

$$u = u', \quad v = \frac{2}{3} v'. \quad (7)$$

For further details, see Eq. 2.

Definition

Color rendering of a light source is the effect of an illuminant on the perceived color of objects by conscious or subconscious comparison with their perceived color under a reference illuminant (CIE S 017:2020 ILV: International Lighting Vocabulary, 2nd edition).

In this content, it is appropriate to define a color rendering index of a light source as a measure of the degree to which the perceived color of an object illuminated by the test illuminant conforms to that of the same object illuminated by the reference illuminant, for specified conditions.

Overview

The color rendering index of the light source is calculated on the basis of the color difference between the tristimulus values of the test-color samples illuminated with the test light source and the tristimulus values of the same test-color sample illuminated with the reference light source having the same correlated color temperature (CCT) as the test light source. For the reference

illuminant, a Planckian radiator is used at low temperatures of 5000 K or less, and CIE daylight illuminant is used at higher than 5000 K, depending on the CCT of the test light source. The special color rendering index R_i is scaled so that $R_i = 100$ is obtained when the tristimulus values of test-color sample i under the test light source are the same as those calculated with respect to the reference illuminant. The general color rendering index R_a is calculated from the arithmetic mean of the special rendering indices for the eight test-color samples $i = 1$ to 8.

Determination of Color Rendering Indices

Figure 1 shows the flow chart to the determination of the CIE color rendering indices (1995). The first step is to select a reference light source. In order to determine a reference illuminant that has the same CCT as the test illuminant, start by calculating the CCT of the test illuminant. Next, the tristimulus values of a test-color sample illuminated with a test light source and those of a reference light source with the same CCT are

CIE Color Rendering Index, Fig. 1 The flow to the determination of the CIE color rendering index

calculated. As the test light source might be deviated from the chromaticity of the reference illuminant along the line of constant CCT, one should allow for chromatic adaptation by means of a von Kries of transformation with reference stimuli. The final step is to calculate the color difference from the tristimulus values of a test-color sample under the test illuminant and those under the reference illuminant. The smaller the color difference, the closer the appearance of the object color under the test light source to that under the reference illuminant. So, the smaller color difference gives the better color rendition. The final formula of the CIE color rendering indices have been calculated based on the color difference between the tristimulus values of a test-color sample under the test light source illuminant and those under the reference illuminant.

Reference Illuminant

The choice of a reference light source compared to the test light source should be governed by whatever is considered to be the original object color perception; that is, color appearance of an object in the light in which it is usually observed. In most practical cases, this light will be incandescent lamp or natural daylight. So, CIE determined that the reference illuminant for light sources with a CCT below 5000 K shall be a Planckian radiator and from 5000 K, one of a series of spectral radiant power distributions of phases of CIE daylight. The reference illuminant is intended to be of the same or nearly the same chromaticity as the test light source. The acceptable chromaticity difference between the test source and the reference illuminant corresponds to 15 MK⁻¹ along the Planckian locus in the chromaticity diagram.

Test-Color Samples

For calculating the CIE general color rendering indices, a set of eight test-color samples is specified in terms of the spectral reflectance. For

CIE Color Rendering Index, Table 1 Munsell notations of the test-color samples

Sample number	Munsell notation	Sample number	Munsell notation
1	7.5R6/4	9	4.5R4/13
2	5Y6/5	10	5Y8/10
3	5GY6/8	11	4.5G5/8
4	2.5G6/6	12	3 PB3/11
5	10BG6/4	13	5YR8/4
6	5 PB6/8	14	5GY4/4
7	2.5P6/8		
8	10P6/8		

calculating the CIE special color rendering indices, any one of the six test-color samples in addition to any one from the above set of eight test-color samples may be used. Their approximate Munsell notations are listed in Table 1.

Color Difference

The color difference between the tristimulus values of the test-color samples illuminated with the test source and the reference illuminant is calculated using the CIE 1964 uniform color space, so called CIE U*V*W* space. The CIE 1964 uniform color space is now outdated and replaces by the CIE 1976 uniform color space, but the color rendering calculations are still performed in the CIE U*V*W* space. The color difference between a test-color sample numbered *i* illuminated by the test and the reference illuminant is denoted as Δ*E_i*.

CIE Color Rendering Indices

A CIE special color rendering index *R_i* is calculated on the basis of the color difference Δ*E_i* for *s* test-color samples *i*, by means of the following formula:

$$R_i = 100 - 4.6\Delta E_i$$

The index *R_i* has been scaled so that *R_i* = 100 is obtained when the tristimulus values of the

test-color sample i under the test source are the same as those calculated with respect to the reference illuminant. So, $R_i = 100$ means the perfect rendition for the test-color sample. The constant factor 4.6 has been selected to give a value of $R_i = 50$ for a traditional warm white fluorescent lamp.

The CIE general color rendering index is defined as the arithmetic mean of the eight test-color samples $i = 1$ to 8:

$$R_a = \frac{1}{8} \sum_{i=1}^8 R_i$$

CIE Guidelines for Evaluation of Gamut Mapping Algorithms: Summary and Related Work (Pub. 156)

Jan Morovic

Hewlett-Packard Company, Sant Cugat del Valles/Barcelona, Catalonia, Spain

Definition

The *CIE Guidelines for the Evaluation of Gamut Mapping Algorithms* (referred to as *Guidelines* in the remainder of this entry) set out experimental conditions under which color gamut mapping algorithms are to be evaluated so that results can be compared and combined from separate experiments. The *Guidelines* were published [1] in 2004 by Division 8 of the CIE and cover a number of aspects of experimental evaluation, both mandatory and optional. They also include case studies for applying them to various color reproduction scenarios and a checklist that can be used to determine an experiment's compliance with the *Guidelines*.

Overview

A color gamut mapping algorithm is that part of a color reproduction process, which ensures that colors from some original (source) are adapted to fit inside the color gamut available under reproduction (destination) conditions. A typical example is a color image viewed on an electronic display that is to be reproduced in print. Here, there are colors that a display can generate (e.g., bright greens), which cannot be matched in print, and a substitution of the out-of-gamut color by an in-gamut color needs to be made. Note that the converse – representing printed colors on a display – also requires gamut mapping, since some printable colors (e.g., cyans) are beyond the capabilities of displays, and that this is the case for the great majority of original–reproduction combinations.

Since gamut mapping can have different aims (e.g., resulting in most similar reproduction to the original or resulting in a most pleasing reproduction), since its performance cannot be measured, and since optimal performance cannot be known in absolute terms, determining how well a gamut mapping algorithm works or whether one algorithm outperforms another is a challenge. Reviewing the literature on this subject [2] prior to the *Guidelines*' publication reveals a great variety of experimental methods and conditions used for comparing alternative gamut mapping algorithms that yielded incomparable but seemingly contradictory conclusions.

The *Guidelines* therefore set out recommendations about the following aspects of a gamut mapping algorithm's evaluation: test images (and their exchange), original and reproduction media, viewing conditions, color measurement, gamut boundary description, a pair of reference gamut mapping algorithms, the color spaces in which they are to be applied, and the psychovisual experimental method to be used. In each of these sections, there are both obligatory aspects and recommended ones, and attention is also paid to how experimental details are to be reported. Finally, the *Guidelines* also show how they are to be applied for specific, typical workflows (Reference Output Medium Metric (ROMM) RGB to print, Cathode-Ray Tube (CRT) to print, and transparency to print), an appendix elaborates on some of the *Guidelines*' sections, and a checklist is provided to determine an experiment's compliance with the *Guidelines*.

Before proceeding to the specifics of experimental evaluation, the *Guidelines* specify the obligatory use of the "subjective accuracy" color reproduction intent, which is defined as aiming at "reproducing a given colour image in a way where the reproduction is as close to the original as possible, this similarity is determined psychophysically and the process has no image enhancing aims." Evaluation of other reproduction intents is not discouraged, but subjective accuracy is mandatory.

Test images are specified first, with the one mandatory image, "Ski" (Fig. 1), made available as a physical transparency, in ROMM RGB and

sRGB (i.e., two colorimetrically defined RGB color spaces) rendered color encodings, and as CIELAB version of these three cases. The *Guidelines* further specify the need to share with the CIE any other test images used in compliant experiments and detail how such sharing is to be done.

Reproductions of the obligatory and other test images then need to be made on a combination of color reproduction media from among the following four types: reflective print, transparency, monitor, and virtual (i.e., wide gamut color spaces such as scRGB [3] or ROMM RGB [4]). Constraints are imposed on acceptable uniformity, repeatability, and viewing geometry-dependent characteristics of these media, and the *Guidelines* also specify which of the media's aspects to report (including measured characterization data).

Given a set of chosen test images, rendered on one medium as originals and to be gamut mapped to another medium, the viewing conditions under which the media are to be viewed are specified next. Here, it is mandatory to report "chromaticity and luminance level of the white point, level and correlated colour temperature of the ambient illumination, light source colour rendering index and nature of field of view (proximal field, background, surround)." A recommendation is made about the original and reproduction images being the same size, the illumination having a color rendering index of at least 90, and the uniformity of illumination dropping off to no less than 75% of central peak illumination. Control over the viewing environment needs to be exercised to exclude extraneous light sources as well as light reflected from objects in it, and specific border and surround characteristics are mandated. Specific luminance levels for different types of media, following ISO 3664 [5], also need to be ensured, and particular care is taken to define aspects of monitor to print matching, where three alternatives are offered for how the two media's white points are to relate: an absolute colorimetric match at D65 chromaticity, an adherence to the per media specifications (i.e., D65 for monitor and D50 for print), or a D65 chromaticity match but at luminance levels as mandated per media.

In terms of color measurement, the requirement is to carry it out as closely to experimental

Specifically, SGCK involves the following transformation for each original color:

1. Keep h_{ab}^* unchanged.
2. Map lightness as follows:

$$L_r^* = (1 - p_C) L_o^* + p_C L_s^* \quad (1)$$

where o refers to the original, r refers to the reproduction, and p_C is a chroma-dependent weight computed from the original color's C^* :

$$p_C = 1 - ((C^{*3}) / (C^{*3} + 5 \times 10^5))^{1/2} \quad (2)$$

and where L_s^* is the result of the original's L_o^* being mapped using the following sigmoidal function (Fig. 2), having x_0 and Σ parameters empirically derived for different levels of reproduction medium minimum L^* (e.g., for a minimum reproduction L^* of 15, $x_0 = 58.2$ and $\Sigma = 35$):

$$S_i = \sum_{n=0}^{n=i} \frac{1}{\sqrt{2\pi\Sigma}} e^{-\frac{(\frac{100n}{\Sigma} - x_0)^2}{2\Sigma^2}} \quad (3)$$

S_i values generate using Function 3 for $i \in [0, m]$ and then form a look-up table that is further scaled using the L^* ranges of the original and reproduction:

$$S_{LUT} = \frac{(S_i - \min(S))}{(\max(S) - \min(S))} (L_{\max r}^* - L_{\min r}^*) + L_{\min r}^* \quad (4)$$

Finally, the L_s^* value needed for Eq. 1 can be

CIE Guidelines for Evaluation of Gamut Mapping Algorithms: Summary and Related Work (Pub. 156), Fig. 2 Sigmoidal function used for L^* mapping (for $x_0 = 58.2$ and $\Sigma = 35$)

obtained by interpolating in the S_{LUT} look-up table with an L_o^* modified as follows:

$$L_{o'}^* = 100 (L_o^* - L_{\min o}^*) / (L_{\max o}^* - L_{\min o}^*) \quad (5)$$

3. The original's C^* and L_r^* obtained from Eq. 1 are next mapped in a plane of constant h_{ab}^* toward the L^* of the cusp (the color with maximum C^* in the reproduction gamut at this h_{ab}^*) as follows:

$$d_r = \begin{cases} d_o; d_o \leq 0.9d_{gr} \\ 0.9d_{gr} + (d_o - 0.9d_{gr})0.1d_{gr}/(d_{go} - 0.9d_{gr}); d_o > 0.9 \times d_{gr} \end{cases} \quad (6)$$

where g refers to gamut boundary, o and r to original and reproduction, and d to distance from the cusp's L^* on the L^* axis (Fig. 3).

Gamut mapping algorithms that are compared among themselves and versus HPMINDE and

SGCK need to be described with sufficient detail for repeatability.

In terms of color spaces in which gamut mapping is to be performed, the *Guidelines* again only require the reporting of whichever space was used. A recommendation is made for isotropic

Work (Pub. 156),**

Fig. 3 L^* and C^* mapping
toward the L^* of the cusp

color spaces that have greater hue uniformity than CIELAB (e.g., IPT [9], ► [CIECAM02](#)).

Finally, the pair comparison, category judgment, and ranking methods are proposed as alternatives for how reproductions made using different gamut mapping algorithms are to be compared visually. Apart from the obligation to use at least 15 observers, there is an extensive list of experimental aspects that need to be reported, and Appendix C provides background on them.

To aid the application of the *Guidelines*, three common scenarios are described in more detail, and recommendations are made for what choices to make in terms of the *Guidelines*' parts. The scenarios are ROMM to print, CRT to print, and transparency to print, and Appendix D includes a checklist that can be completed to test compliance with the *Guidelines*.

Future Directions

The *Guidelines* have been used extensively since their publication in 2004 to inform the design and execution of the experimental evaluation of gamut mapping algorithms. A notable aspect of these experiments is the use of greater numbers of test images, such as 15 [10], 20 [11], and even 250 [12], as compared to the previous trend of using around five, which has contributed to a general unreliability of results. The *Guidelines* have also been used by a large-scale evaluation

of nine printer manufacturers' products reported by Fukasawa et al. [13]. Since they were formulated close to 10 years ago, there are aspects of the *Guidelines*, e.g., their reference to CRTs and film transparencies and lack of reference to wide gamut displays, which would benefit from future revision. The *Guidelines* also prepared the ground for interrelating the results of multiple, compliant experiments, which too is yet to be implemented.

CIE Guidelines for Mixed Mode Illumination: Summary and Related Work

Suchitra Sueeprasan

Department of Imaging and Printing Technology,
Chulalongkorn University Intellectual
Repository, Chulalongkorn University, Bangkok,
Thailand

Synonyms

Mixed adaptation condition; Mixed chromatic adaptation

Definition

Mixed mode illumination refers to an image comparison between softcopy and hardcopy with successive binocular viewing. When comparing the softcopy images on self-luminous displays with the hardcopy images under ambient lighting, an observer's eyes move back and forth between the images. Under such circumstance, the state of adaptation is unfixed and the human visual system partially adapts to the white point of the softcopy

display and partially adapts to the ambient illumination. The term *mixed chromatic adaptation* is defined as a state in which observers adapt to light from sources of different chromaticities [3].

Background

In 1998, the Technical Committee 8–04, Adaptation under Mixed Illumination Conditions, was formed in Commission Internationale de l'Eclairage (CIE)/Division 8 (Image Technology), with the aim to investigate the state of adaptation of the visual system when comparing softcopy images on self-luminous displays and hardcopy images viewed under various ambient lighting conditions. A number of experiments were conducted with the goal to achieve color appearance matches between softcopy and hardcopy images under mixed illumination conditions. Katoh [5–7] developed the mixed adaptation model, namely, S-LMS, for such application. In his study, softcopy images on a CRT were compared with hardcopy images under F6 illumination. Under equal luminance levels of softcopy and hardcopy, it was found that the human visual system was 60% adapted to the monitor's white point and 40% to the ambient light. The same adaptation ratio was also found for unequal luminance levels. It is concluded that the adaptation ratio was independent of image content, luminance, and chromaticity of the monitor's white point and the ambient illumination.

The study by Berns and Choh [1], in which softcopy images were compared with hardcopy images under F2 illuminant with equal luminance levels, showed that an image with a chromatic adaptation shift of 50% was most preferred as the closest color match and the best stand-alone image. The color model tested in this study was the RLAB color space. Shiraiwa et al. [9] proposed a new method in which the mixed chromatic adaptation was applied in CIE xy chromaticity coordinates. The best adaptation ratio was between 50% and 60%, which is similar to the previous studies. In the visual experiments, where the illuminants of softcopy and hardcopy images were different, their proposed method and

the S-LMS model, both incorporating the mixed adaption, generated better color appearance matches than the conventional color management systems.

Henley and Fairchild [4] tested the performance of various color models with the inclusion and exclusion of mixed adaptation. Observers made appearance matches of color patches on a CRT to hardcopy originals under six different matching methods. The results were reported in terms of color differences between the actual match and the predicted match by color models. The models incorporating the mixed adaptation improved the results in all conditions over their corresponding conventional models.

The studies by Katoh and Nakabayashi [8] and Sueeprasan and Luo [10] closely followed the experimental guidelines put forth by TC8–04. In the experiments, softcopy and hardcopy images were compared using the simultaneous binocular matching technique. Various color models were tested. In Katoh and Nakabayashi's study, the linear transformation matrix in the S-LMS model was replaced by different chromatic adaptation transform matrices. The results showed that the S-LMS model with the Bradford (BFD) matrix performed best. They also investigated whether incomplete adaptation was needed in the mixed chromatic adaptation model. RLAB method and D factor resulted in much better score than complete adaptation, indicating that the incomplete adaptation was essential.

In Sueeprasan and Luo's study, the performance of the promising chromatic adaptation transforms (CMCCAT97, CMCCAT2000, and CIECAT94) and the S-LMS mixed chromatic adaptation transform was compared. The state of chromatic adaptation was also investigated. The results showed that the incomplete adaptation ratio was crucial in producing color matches. The human visual system was between 40% and 60% adapted to the white point of the monitor regardless of the changes in illumination conditions. CMCCAT2000 outperformed the other models.

The results from the previous studies are in good agreement for the chromatic adaptation ratio, which is in the range of 40–60% adapted

to the white point of the monitor. The adaptation ratio is consistent over various viewing conditions and regardless of the chromatic adaptation transform and incomplete adaptation formula used. Both incomplete and mixed chromatic adaptations are required in the mixed adaptation model for predicting color matches under mixed illumination conditions. Based on these findings, TC8–04 recommends the mixed adaptation model for use in cross-media color reproduction when mixed illumination conditions are employed.

Recommended Model

CIE TC8–04 recommends the S-LMS mixed adaptation model for achieving appearance matches under mixed chromatic adaptation. The S-LMS model is fundamentally a modified form of the von Kries transformation with incorporation of partial adaptation. The compensation for chromatic adaptation includes incomplete adaptation and mixed adaptation.

The first step of the S-LMS model is to transform XYZ tristimulus values to the cone signals for the human visual system (Eqs. 1, 2, and 3). $X_n Y_n Z_n$ values are tristimulus values of the reference white. M_{CAT02} is the chromatic adaptation transformation matrix used in CIECAM02 [2].

$$\begin{bmatrix} L \\ M \\ S \end{bmatrix} = M_{CAT02} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (1)$$

$$\begin{bmatrix} L_{n(CRT)} \\ M_{n(CRT)} \\ S_{n(CRT)} \end{bmatrix} = M_{CAT02} \begin{bmatrix} X_{n(CRT)} \\ Y_{n(CRT)} \\ Z_{n(CRT)} \end{bmatrix} \quad (2)$$

$$M_{CAT02} = \begin{bmatrix} 0.7328 & 0.4296 & -0.1624 \\ -0.7036 & 1.6974 & 0.0061 \\ 0.0030 & 0.0136 & 0.9834 \end{bmatrix} \quad (3)$$

Then, compensation is made for the change in chromatic adaptation according to the

surroundings. The human visual system changes the cone sensitivity of each channel to compensate for the change in illumination. In the calculation, the signals of each channel are divided by those of the adapted white. There are two steps of calculation to obtain the adapted white of a monitor.

The first step is the compensation for the incomplete adaptation of the visual system to the self-luminous displays (Eq. 4). Even if the monitor is placed in a totally dark room, the chromatic adaptation of the human visual system to the white point of the monitor will not be complete. That is, the reference white of the monitor does not appear perfectly white. Chromatic adaptation becomes less complete as the chromaticity of the adapting stimulus deviates from the illuminant E and as the luminance of the adapting stimulus decreases. The D factor from CIECAM02 is used (Eq. 5). F is 1.0, and L_A is the absolute luminance of the adapting field.

$$\begin{aligned} L'_{n(\text{CRT})} &= L_{n(\text{CRT})} / \{D + L_{n(\text{CRT})}(1 - D)\} \\ M'_{n(\text{CRT})} &= M_{n(\text{CRT})} / \{D + M_{n(\text{CRT})}(1 - D)\} \\ S'_{n(\text{CRT})} &= S_{n(\text{CRT})} / \{D + S_{n(\text{CRT})}(1 - D)\} \end{aligned} \quad (4)$$

$$D = F \left\{ 1 - \left(\frac{1}{3.6} \right) e^{\left(\frac{L_A - 42}{92} \right)} \right\} \quad (5)$$

The next step is the compensation for mixed adaptation. In cases where the white points of the monitor and the ambient light are different, it was hypothesized that the human visual system is partially adapted to the white point of the monitor and partly to the white point of the ambient light. Therefore, the adapting stimulus for softcopy images can be expressed as the intermediate point of the two (Eqs. 6 and 7). It should be noted that incompletely adapted white is used for the white point of the monitor. $Y_{n(\text{CRT})}$ is the absolute luminance of the white point of the monitor, and Y_{ambient} is the absolute luminance of the ambient light.

$$\begin{aligned} L''_{n(\text{CRT})} &= R_{\text{adp}} \cdot \left(\frac{Y_{n(\text{CRT})}}{Y_{\text{adp}}} \right)^{1/3} \cdot L'_{n(\text{CRT})} \\ &\quad + (1 - R_{\text{adp}}) \cdot \left(\frac{Y_{\text{ambient}}}{Y_{\text{adp}}} \right)^{1/3} \cdot L_{\text{ambient}} \\ M''_{n(\text{CRT})} &= R_{\text{adp}} \cdot \left(\frac{Y_{n(\text{CRT})}}{Y_{\text{adp}}} \right)^{1/3} \cdot M'_{n(\text{CRT})} \\ &\quad + (1 - R_{\text{adp}}) \cdot \left(\frac{Y_{\text{ambient}}}{Y_{\text{adp}}} \right)^{1/3} \cdot M_{\text{ambient}} \\ S''_{n(\text{CRT})} &= R_{\text{adp}} \cdot \left(\frac{Y_{n(\text{CRT})}}{Y_{\text{adp}}} \right)^{1/3} \cdot S'_{n(\text{CRT})} \\ &\quad + (1 - R_{\text{adp}}) \cdot \left(\frac{Y_{\text{ambient}}}{Y_{\text{adp}}} \right)^{1/3} \cdot S_{\text{ambient}} \end{aligned} \quad (6)$$

$$Y_{\text{adp}} = \left\{ R_{\text{adp}} \cdot Y_{n(\text{CRT})}^{1/3} + (1 - R_{\text{adp}}) \cdot Y_{\text{ambient}}^{1/3} \right\}^3 \quad (7)$$

When the luminance of the monitor, $Y_{n(\text{CRT})}$, equals the ambient luminance, Y_{ambient} , the adapting white can be calculated by Eq. 8.

$$\begin{aligned} L''_{n(\text{CRT})} &= R_{\text{adp}} \cdot L'_{n(\text{CRT})} + (1 - R_{\text{adp}}) \cdot L_{\text{ambient}} \\ M''_{n(\text{CRT})} &= R_{\text{adp}} \cdot M'_{n(\text{CRT})} + (1 - R_{\text{adp}}) \cdot M_{\text{ambient}} \\ S''_{n(\text{CRT})} &= R_{\text{adp}} \cdot S'_{n(\text{CRT})} + (1 - R_{\text{adp}}) \cdot S_{\text{ambient}} \end{aligned} \quad (8)$$

R_{adp} is the adaptation ratio to the white point of the monitor. When the ratio R_{adp} equals 1.0, the human visual system is assumed to be fully adapted to the white point of the monitor and none to the ambient light. Conversely, when the ratio is 0.0, the human visual system is assumed to be completely adapted to the ambient light and none to the white of the monitor. These two extreme cases assume that the human visual system is at single-state chromatic adaptation. For mixed chromatic adaptation, 0.6 is chosen for R_{adp} in the S-LMS model.

With the newly defined white points for the softcopy images, the von Kries chromatic adaptation model is applied. The cone signals after adaptation are calculated as Eq. 9.

$$\begin{aligned} L_s &= L_{(\text{CRT})}/L''_{n(\text{CRT})} \\ M_s &= M_{(\text{CRT})}/M''_{n(\text{CRT})} \\ S_s &= S_{(\text{CRT})}/S''_{n(\text{CRT})} \end{aligned} \quad (9)$$

For hardcopy images, the simple von Kries chromatic adaptation without incomplete chromatic adaptation and mixed chromatic adaptation is used (Eq. 10). The paperwhite is chosen as the reference white, because the eye tends to adapt according to the perceived whitest point of the scene.

$$\begin{aligned} L_s &= L_{(\text{Print})}/L_{n(\text{Print})} \\ M_s &= M_{(\text{Print})}/M_{n(\text{Print})} \\ S_s &= S_{(\text{Print})}/S_{n(\text{Print})} \end{aligned} \quad (10)$$

Implementation

The S-LMS mixed adaptation model is designed to integrate into the CIECAM02 model, which is developed for color management applications. Hence, the S-LMS model should be applied to extend the CIECAM02 model for use in cross-media color reproduction when mixed mode illumination is employed. The input parameters required are XYZ tristimulus values of the white point of the monitor, the adopted white for the ambient light, and the paper white of hardcopy.

CIE Method of Assessing Daylight Simulators

Robert Hirschler
Colour Consultant, Budapest, Hungary

Definition

Daylight simulator is a “device that provides spectral irradiance approximating that of a CIE standard daylight illuminant or CIE daylight illuminant, for visual appraisal or measurement of colours” [1].

Development of the CIE Methods of Assessing Daylight Simulators

Although for decades after the acceptance of the CIE system (1931), Illuminant C was accepted and widely used in colorimetry, the practical implementation of Source C was limited to special laboratory use. In 1963, the Colorimetry Committee of the CIE decided to supplement the then existing CIE illuminants A, B, and C by new illuminants more adequately representing phases of natural daylight. These new illuminants (D55, D65, and D75) were defined by a new approach suggested by Judd et al. [2] based on Simonds' [3] method of reducing experimental data to characteristic vectors (eigenvectors) and calculating the relative spectral power distribution of daylight of any desired correlated color temperature.

As a consequence of this new approach, the new daylight illuminants have been defined theoretically (albeit based on experimental data), and it means that there are still no physically realizable light sources corresponding to the illuminants. It was clear to the CIE already in 1967 that daylight simulators were required that would serve as standard sources representing the daylight illuminants. As a first step, Wyszecki [4] published spectral irradiance distribution data on a number of daylight simulators and also suggested methods for evaluating how well these sources simulated the corresponding illuminants.

When asking the question "how close" a given source is to the illuminant of the same correlated color temperature, we must first decide how to measure this closeness.

The "fingerprints" of illuminants and light sources are their spectral power distributions, and for most of the colorimetric calculations, only the relative values are interesting, calculated from the spectral radiance or irradiance values and normalized to have the value of 100 at 560 nm or to have $Y = 100$.

The colorimetric properties of illuminants and light sources are generally described in terms of the x, y or u', v' chromaticity coordinates, the correlated color temperature, and very often the color rendering index. Although these properties may often give us sufficient information, for the more

specific purpose of evaluating whether a given light source may or may not be considered an adequate realization (simulation) of the corresponding illuminant, more complex measures are needed. By and large, they can be divided into two groups: those comparing the spectral curves with or without applying weights to take the visual significance into consideration and those measuring the effect of the illumination on a selected group of object colors and then comparing either the change from one illuminant to the other (color rendering index or CRI type) or by calculating the color difference under the test source illuminant for pairs of samples which are perfect matches under the reference illuminant (metamerism index or MI type). In the early 1970s, a subcommittee of TC-1.3 on Standard Sources studied a number of proposals for different methods: based on MI-type indices for the visible range [5–7] and based on the effective excitation of three fluorescent samples for the UV range [8]. At the Troy (1977) meeting of TC-1.3, a modification of the Ganz [9] proposal was adopted for the UV range evaluation: the method used three virtual metameric (isomeric) pairs for each illuminant, each consisting of a fluorescent and a nonfluorescent sample.

The recommendations of TC-1.3 were first published in 1981 as Publication CIE 51 [10], amended in 1999 (Publication 51.2) [11], and published as CIE Standard S 012 in 2004 [1].

Chromaticity Limits of Daylight Simulators

As a preliminary requirement for a light source to be considered a simulator of a CIE daylight illuminant, its chromaticity coordinates must be within a specified range from the chromaticity coordinates of the illuminant. The allowable range in the CIE 1976 Uniform Chromaticity Scale diagram u_{10}', v_{10}' is a circle of radius 0.015 centered on the point representing the illuminant concerned. Figure 1 shows the allowable gamuts of chromaticity for CIE Standard Illuminant D65 and CIE illuminants D55 and D75.

CIE Method of Assessing Daylight Simulators,

Fig. 1 Allowable range of chromaticity of daylight simulator for selected CIE illuminants on the CIE 1976 Uniform Chromaticity Scale diagram u'_{10}, v'_{10}

As evaluated by the chromaticity limits both illuminants D55 and D75 are acceptable as simulators for Standard Illuminant D65, and D65 is acceptable as a simulator of both D55 and D75 (see also the category limits).

Visible Range Evaluation of Daylight Simulators

The method is based on the evaluation of the Special Metamerism Index: change in illuminants of five metameric pairs representative of practical samples in related industries. CIELAB coordinates of these sample pairs are calculated for the reference illuminant and the simulator source. The color difference between each standard and the respective comparison specimen is very near to zero for the reference illuminant; the average color difference for the five pairs under the simulator gives the quality grade for the daylight simulator.

Figure 2 illustrates the spectral radiance factors of the five standard specimens for visible range assessment based on the tables published in the CIE Standard [1].

The standard specimens are the same for every illuminant, while there are different comparison specimens for each illuminant. Figure 3 shows the

spectral radiance factors of the first standard specimen and those of the metameric comparison specimens for D50, D65 resp. D75.

For the calculation of the visible range metamerism index M_v , the relative spectral irradiance of the simulator has to be determined in the 380–780 nm wavelength range at 5 nm intervals and over 5 nm bands and normalized so that the assessment is independent of the absolute value of irradiance. (As data are generally needed also for the determination of the UV range index, the measurements are performed, whenever viable, in the 300–780 nm range.) Tristimulus values and CIELAB coordinates are then calculated in the usual way for the five metameric pairs, and the average of the five color differences gives the visible range metamerism index M_v . The visible range quality grade is calculated according to Table 1.

The visible range quality classification of daylight simulators is thus calculated through the following steps:

- Determine the relative spectral irradiance of the light source in the 380–780 nm range.
- Calculate the tristimulus values and the CIELAB coordinates for each of the five standards and the five comparison specimens under

CIE Method of Assessing Daylight Simulators,

Fig. 2 Spectral radiance factors of the five standard specimens for visible range assessment

CIE Method of Assessing Daylight Simulators,

Fig. 3 Spectral radiance factors of the first standard specimen and those of the metameric comparison specimens for D50, D65 resp. D75 for visible range assessment

- the reference illuminant and under the test light source.
- Calculate the CIELAB color differences between each standard and the respective comparison specimen under reference illuminant (should be near zero) and under the test light source.
 - Calculate the average of the five color difference values.

- Determine the quality grade using Table 1.

Ultraviolet Range Evaluation of Daylight Simulators

Following the recommendation by Ganz [9], three “metameric” pairs are defined: three fluorescent standard specimens by their spectral external

radiant efficiency $Q(\lambda')$ (Fig. 4), the relative spectral distribution of radiance due to fluorescence $F(\lambda)$ (Fig. 5), and spectral reflected radiance factor $\beta_R(\lambda)$ (Fig. 6); and three nonfluorescent comparison specimens by their spectral (reflected) radiance factors (Fig. 7) (In fact, these pairs are not truly *metameric* rather *isomeric* as they are spectrally identical under the respective daylight illuminants).

The CIE document states, “ $Q(\lambda')$ is the ratio of the total radiant power emitted by the fluorescent process for an excitation wavelength λ' to the total radiant excitation power irradiating the fluorescent material” [1]. The total excitation N of the fluorescent standard specimens is computed by Eq. 1:

$$N = \sum_{300}^{460} S_n(\lambda') \cdot Q(\lambda') \cdot \Delta\lambda' \tag{1}$$

where $S_n(\lambda')$ is the normalized spectral irradiance of the simulator in the spectral region from 300 nm to 460 nm, $Q(\lambda')$ is the spectral external radiant efficiency of the fluorescent specimen over the same spectral range, as shown in Fig. 4, and $\Delta\lambda'$ is the wavelength interval of 5 nm.

$F(\lambda)$ is the ratio of the spectral distribution of radiance due to fluorescence to the sum of the tabulated values of this distribution, that is, $\sum \lambda F(\lambda) = 1.0$. $F(\lambda)$ is identical for the three fluorescent standard specimens and is independent of the SPD of the illumination.

The spectral fluorescent radiance factor $\beta_F(\lambda)$ is computed by Eq. 2:

$$\beta_F(\lambda) = \frac{N \cdot F(\lambda)}{S_n(\lambda)} \tag{2}$$

CIE Method of Assessing Daylight Simulators,
Table 1 Quality classification of daylight simulators [1]

Quality grade	Metamerism index
	Mv or Mu
A	≤ 0.25
B	$> 0.25 - 0.50$
C	$> 0.50 - 1.00$
D	$> 1.00 - 2.00$
E	> 2.00

where N is the total excitation computed by Eq. 1, $F(\lambda)$ is the relative spectral distribution of radiance due to fluorescence as shown in Fig. 5, and $S_n(\lambda)$ is the normalized spectral irradiance distribution of the simulator.

$\beta_R(\lambda)$ is the ratio of the radiance due to the reflection of the medium in the given direction to

CIE Method of Assessing Daylight Simulators,
Fig. 4 Spectral external radiant efficiency $Q(\lambda')$ for the three UV standards (based on data from [1])

CIE Method of Assessing Daylight Simulators,

Fig. 5 Relative spectral distribution of radiance due to fluorescence $F(\lambda)$ for the three UV standards

CIE Method of Assessing Daylight Simulators,

Fig. 6 Spectral reflected radiance factor $\beta_R(\lambda)$ for the three UV standards

the radiance of a perfect reflected diffuser identically irradiated [1].

The sum of $\beta_R(\lambda)$ and $\beta_F(\lambda)$ gives the total radiance factor $\beta_T(\lambda)$:

$$\beta_T(\lambda) = \beta_R(\lambda) + \beta_F(\lambda) \quad (3)$$

as illustrated in Fig. 7.

As can be seen from the definition equations, the $\beta_F(\lambda)$ and thus the $\beta_T(\lambda)$ values depend on the

SPD of the illumination, so we would have curves for the other CIE illuminants different from those in Fig. 7.

The comparison specimens are not fluorescent; the spectral reflected radiance factors are tabulated for each CIE illuminant, as illustrated in Fig. 8 for the third specimen.

The UV standard and the UV comparison specimens are isomeric, that is, they are practically identical when illuminated by the reference

CIE Method of Assessing Daylight Simulators,

Fig. 7 Total spectral radiance factor $\beta_T(\lambda)$ for the three UV standards for illuminant D65

CIE Method of Assessing Daylight Simulators,

Fig. 8 Spectral reflected radiance factor of the first comparison specimen for the four CIE illuminants

illuminants. Thus, the UV standard 3 curve for D65 from Fig. 7 is the same as the comparison specimen 3 curve for D65 from Fig. 8. In Fig. 9, we see both curves (dotted and dashed lines) together with the standard 3 curve under a daylight simulator (solid line).

When calculating the UV range metamerism index M_u , the total radiance factor for the standard is calculated for the test source, and the spectral

(reflected) radiance factor for the comparison specimen is selected for the reference illuminant. The UV range quality classification of daylight simulators is thus calculated through the following steps:

- Determine the relative spectral irradiance of the light source $S(\lambda)$ in the 300–700 nm range.

CIE Method of Assessing Daylight Simulators,

Fig. 9 Total spectral radiance factor $\beta_T(\lambda)$ for UV standard 3 under D65 and under a quality grade BC (filtered tungsten lamp with additional UV) simulator; and for comparison specimen 3 for illuminant D65

- Take $Q(\lambda')$ for each of the three standards from the data illustrated in Fig. 4.
- Calculate N for each of the three standards from Eq. 1.
- Take the $F(\lambda)$ values for each of the three standards from the data illustrated in Fig. 5.
- Calculate $\beta_F(\lambda)$ for each of the three standards from Eq. 2.
- Take $\beta_R(\lambda)$ for each of the three standards from the data illustrated in Fig. 6.
- Calculate $\beta_T(\lambda)$ for each of the three standards from Eq. 3 as illustrated in Fig. 7.
- Take the spectral (reflected) radiance factors for the three comparison specimens (like those illustrated in Fig. 8 for specimen 3).
- Calculate the tristimulus values and the CIELAB coordinates for each of the three standards and the three comparison specimens under the reference illuminant and under the test light source.
- Calculate the CIELAB color differences between each standard and the respective comparison specimen under the reference illuminant (should be near zero) and under the test light source.
- Calculate the average of the three color difference values under the test light source.
- Determine the quality grade using Table 1.

In the example illustrated in Fig. 9, $Mu = 0$ for D65 (standard and comparison specimens are identical); $Mu = 0.79$ (quality grade C).

Practical Application of the CIE Method

In the case of color measuring spectrophotometers measuring nonfluorescent samples, the SPD of the light source has no relevance only for their visual evaluation. For fluorescent samples, both the visible and the UV range evaluation are of importance. When classifying daylight simulators, generally both quality grades are given: first the visible range metamerism index Mv , then the UV range index Mu . According to the CIE standard [1], “daylight simulators having [BC] grades have been found useful for many applications.” It is also interesting to note here that both illuminants D55 and D75 classify as grade CC simulators, while illuminant D50 is a grade DD simulator of the D65 standard illuminant.

Some national and international standards, for example, [12] also consider quality grade BC as acceptable for critical match in visual evaluations. For the classification of instruments, the ASTM Standard Practice 991–11 [13] states that the “requirement that the instrument simulation of CIE D65 shall have a rating not worse than BB

(CIELAB) as determined by the method of CIE Publication 51 has often been referenced.” This standard comes with the caveat that “the method of CIE 51 is only suitable for ultraviolet excited specimens evaluated for the CIE 1964 (10°) observer. The methods described in CIE 51 were developed for UV activated fluorescent whites and have not been proven to be applicable to visible-activated fluorescent specimens.”

There are different technologies available for realizing daylight simulators for visual assessment: filtered tungsten lamps, dichroic lamps, filtered short-arc xenon lamps, fluorescent lamps, and LED-based lamps. In color measuring spectrophotometers, filtered pulsed xenon lamps are used nearly exclusively as daylight simulator sources. A detailed description and evaluation of the different implementations was described in CIE Publication no. 192 [14] and some additional details in [15].

Many of the commercially available booths for visual assessment under D65 are quality grade BC to BE, that is, they are acceptable daylight simulators in the visible range, but only one with fluorescent lamps and one with filtered tungsten and additional UV lamps were found to be acceptable in the UV range. For D50 and D75, the results were even worse; none complied with quality grade BC criterion. Well-calibrated color measuring spectrophotometers can have excellent (quality grade AB or BA) D65 simulators, but there are no reports of instruments equipped with D50 or D75 simulators [14, 15].

CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams

Andrew Stockman

Department of Visual Neuroscience, UCL
Institute of Ophthalmology, London, UK

Synonyms

CIE cone fundamentals; CIE fundamental color matching functions; Cone fundamentals, Stockman-Sharpe

Definition

Because each of the long-, middle-, and short-wavelength-sensitive (L, M, and S) cone types responds univariantly to light, human color vision and human color matches are trichromatic. Trichromatic color matches depend on the spectral sensitivities of the three cones, which are also known as the fundamental color matching functions (or CMFs): $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$. The spectral sensitivity of each cone reflects how its sensitivity changes with wavelength. Measured at the cornea, the L-, M-, and S-cone quantal spectral sensitivities peak at approximately 566, 541, and 441 nm, respectively. These fundamental CMFs are the physiological bases of other measured CMFs, all of which should be linear transformations of the fundamental CMFs.

The CIE [1] has now explicitly defined a standard set of physiologically based fundamental CMFs (or cone fundamentals) by adopting the estimates of Stockman and Sharpe [2] for 2- and 10-deg vision. These estimates were based on psychophysical measurements made in normal trichromats, red-green dichromats, blue-cone monochromats, and tritanopes all of known genotype; and from a direct analysis of the color matching data of Stiles and Burch [3].

The 10-deg cone fundamentals are defined as linear combinations of the 10-deg CMFs of Stiles and Burch [3] with some adjustments to $\bar{s}(\lambda)$ at longer wavelengths. The 2-deg cone fundamentals are similarly defined, but have also been adjusted to be appropriate for 2-deg vision.

The CIE cone fundamentals are physiologically based in the sense that they reflect the spectral sensitivities of the cone photoreceptors, the initial physiological transducers of light. In principle, any set of CMFs can be linearly transformed back to the fundamental CMFs. The popular CIE 1931 CMFs, however, are substantially flawed especially at shorter wavelengths, so they cannot be used to accurately model the cone photoreceptors or indeed human color vision. One of the many advantages of using physiologically relevant functions is that they can be easily extended to represent the postreceptoral transformation of the cone signals to chromatic (L-M and S-[L + M]) and achromatic (L + M) signals.

In addition to $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$, the CIE standard also defines the photopic luminous efficiency function [$V(\lambda)$ or $\bar{y}(\lambda)$] for 2-deg and 10-deg vision as linear combinations of $\bar{l}(\lambda)$ and $\bar{m}(\lambda)$. This facilitates the further transformation of $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ to physiologically relevant versions of the more familiar CMFs: $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, for which $\bar{y}(\lambda)$ is the luminous efficiency function and $\bar{z}(\lambda)$ is a scaled version of $\bar{s}(\lambda)$.

Overview

A consequence of trichromacy is that the color of any light can be specified as the intensities of the three primary lights that match it. The bottom left-hand panel of Fig. 1 shows $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs for **RGB** (red-green-blue) primaries of 645, 526, and 444 nm. Each CMF defines the amount of that primary required to match monochromatic test lights of equal energy. CMFs, such as these, can be determined directly. CMFs can be linearly transformed to any other set of real primary lights and to imaginary primary lights, such as the **LMS** cone fundamental primaries (or “Grundempfindungen” – fundamental sensations) shown in the bottom right-hand panel of Fig. 1, which are the physiologically relevant cone spectral sensitivities, or to the still popular **XYZ** CMFs shown in the top panel. The three fundamental primaries correspond to the three imaginary primary lights that would uniquely stimulate each of the three cones and yield the $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ fundamental CMFs. All other CMF sets depend on the fundamental CMFs and should be a linear transformation of them.

A definition of the fundamental CMFs requires two things: first, an accurate set of representative $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ CMFs that can be linearly transformed to give the $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ CMFs and, second, a knowledge of the coefficients of the transformation from one to the other. Stockman and Sharpe [2] obtained the coefficients of the transformation primarily by fitting linear combinations of $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ to spectral sensitivity measurements made in red-green dichromats, blue-cone monochromats, and normals and in the case of the S-cones also by analyzing the CMFs themselves (see below).

CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams, Fig. 1 CMFs can be linearly transformed from one set of primaries to another.

Shown here are 10-deg CMFs for real, spectral **RGB** primaries [3] and for the CIE physiologically relevant **LMS** cone fundamental primaries and **XYZ** primaries

Choice of “Physiologically Relevant” RGB CMFs

Of critical importance in the definition of the cone fundamentals is the choice of CMFs from which they are transformed. The ones that are available vary considerably in quality. The most widely used, the CIE 1931 2-deg CMFs [4], are the least secure. Based only on the *relative* color matching data of Wright [5] and Guild [6], these CMFs were reconstructed by assuming that their linear combination must equal the 1924 CIE $V(\lambda)$ function [4, 7]. Not only is this assumption unnecessary, since CMFs can be measured directly, but the CIE $V(\lambda)$ curve used in the reconstruction is far too insensitive at short wavelengths. Thus, the CIE 1931 CMFs are a poor choice for defining the cone fundamentals.

By contrast, the Stiles and Burch 2-deg [8] and 10-deg [3] CMFs are directly measured functions. Although referred to by Stiles as “pilot” data, the 2-deg CMFs are the most extensive set of directly

measured data for 2-deg vision available, being averaged from matches made by ten observers. They are used as an intermediate step in the derivation of the cone fundamentals (see below).

The most secure and comprehensive set of directly measured color matching data are the large-field, centrally viewed 10-deg CMFs of Stiles and Burch [3]. They were measured in 49 subjects from approximately 390–730 nm (and in nine subjects from 730 to 830 nm). Consequently, the 10-deg CMFs of Stiles and Burch have been chosen as the basis for defining the “physiologically relevant” cone fundamentals. The downside of using 10-deg CMFs to model 2-deg spectral sensitivity data is that the spectral sensitivities must be corrected for the differences in preretinal filtering and in photopigment optical density between a 2-deg and 10-deg viewing field. However, such adjustments are straightforward once the spectral sensitivities are known (for details and formulae, see [9]).

Note that the Stiles and Burch [3] 10-deg CMFs are preferable to the large-field 10-deg CIE 1964 CMFs, which, although based mainly on the 10-deg CMFs of Stiles and Burch [3], were compromised by the inclusion of the Speranskaya [10] 10-deg data and by several adjustments carried out by the CIE (see [2]).

Spectral Sensitivity Measurements

Figures 2 and 3 show the spectral sensitivity measurements from which the coefficients of the transformation to the cone fundamentals were obtained. They were measured using a 2-deg target field. Figure 2 shows the mean L- and M-cone measurements made in red-green dichromats of known genotype: deuteranopes, who lack M-cone function, either with serine (red circles) or alanine (orange and yellow squares) at position 180 of their L-cone photopigment opsin gene (these are the two commonly occurring genetic polymorphisms in the normal population that cause a slight shift in peak wavelength of the L-cone pigment), and protanopes (green diamonds), who lack L-cone. A short-wavelength chromatic adapting light eliminated any S-cone contribution to the measurements. For further details, see [11].

The upper panel of Fig. 3, below, shows the mean S-cone spectral sensitivity measurements (blue circles) made in three blue-cone monochromats, who lack L- and M-cones, and at wavelengths shorter than 540 nm in five normal subjects by Stockman, Sharpe, and Fach [12]. In normals, an intense yellow background field selectively adapted the M- and L-cones, so revealing the S-cone response at wavelengths up to 540 nm.

These spectral sensitivity measurements were then used to find the linear combinations of $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ that best fit each of the three cone spectral sensitivities, $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$, allowing adjustments in the densities of pre-receptoral filtering and photopigment optical density in order to account for differences in the mean densities between different populations and to account for differences in the retinal area (see [9]).

CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams, Fig. 2

Mean cone spectral sensitivity data and fits of the CMFs. L-cone data from deuteranopes with either L(ser¹⁸⁰) (red circles, $n = 17$) or 5 L(ala¹⁸⁰) (yellow squares, $n = 2$; orange squares, $n = 3$) and M-cone data from protanopes (green diamonds, $n = 9$) measured by Sharpe et al. [11] and the linear combinations of the Stiles and Burch 2-deg CMFs [8] (continuous lines) that best fit them. The dichromat data have been adjusted in macular and lens density to best fit the CMFs. One group of L(ala¹⁸⁰) subjects did not make short-wavelength measurements. Error bars are ± 1 standard error of the mean. For best-fitting values, see Stockman and Sharpe [2]

The significance of the best-fitting linear combinations can be stated formally: When an observer matches the test and mixture fields in a color matching experiment, the two fields cause identical absorptions in each of his or her three cone types. The match, in other words, is a match at the level of the cones. The matched test and mixture fields appear identical to S-cones, to M-cones, and to L-cones. For matched fields, the following relationships apply:

$$\begin{aligned} \bar{l}_R \bar{r}(\lambda) + \bar{l}_G \bar{g}(\lambda) + \bar{l}_B \bar{b}(\lambda) &= \bar{l}(\lambda), \\ \bar{m}_R \bar{r}(\lambda) + \bar{m}_G \bar{g}(\lambda) + \bar{m}_B \bar{b}(\lambda) &= \bar{m}(\lambda), \\ \bar{s}_R \bar{r}(\lambda) + \bar{s}_G \bar{g}(\lambda) + \bar{s}_B \bar{b}(\lambda) &= \bar{s}(\lambda), \end{aligned} \quad (1)$$

CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams,

Fig. 3 *Top:* Mean S-cone spectral sensitivity measurements of Stockman, Sharpe, and Fach [12] and linear combination of the Stiles and Burch 2-deg CMFs that best fits them (≤ 565 nm), after applying lens and macular pigment density adjustments (blue circles). *Bottom left:* Stiles and Burch green and blue 2-deg chromaticity coordinates (blue squares). The best-fitting straight line from 555 nm to long wavelengths has a slope of -0.01625 . *Bottom right:* Stiles and Burch green and blue 10-deg chromaticity coordinates (light blue diamonds). The best-fitting straight line from 555 nm to long wavelengths has a slope of -0.0106

where $\bar{l}_R$, $\bar{l}_G$, and $\bar{l}_B$ are, respectively, the L-cone sensitivities to the R, G, and B primary lights and similarly $\bar{m}_R$, $\bar{m}_G$, and $\bar{m}_B$ and $\bar{s}_R$, $\bar{s}_G$, and $\bar{s}_B$ are the analogous L-, M-, and S-cone sensitivities. Since the S-cones are insensitive in the red part of the spectrum, it can be assumed that $\bar{s}_R$ is effectively zero for the long-wavelength R primary. There are therefore eight unknowns required for the linear transformation:

$$\begin{pmatrix} \bar{l}_R & \bar{l}_G & \bar{l}_B \\ \bar{m}_R & \bar{m}_G & \bar{m}_B \\ 0 & \bar{s}_G & \bar{s}_B \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} = \begin{pmatrix} \bar{l}(\lambda) \\ \bar{m}(\lambda) \\ \bar{s}(\lambda) \end{pmatrix}. \quad (2)$$

Since we are concerned about only the relative shapes of $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$, the eight unknowns collapse to just five:

$$\begin{pmatrix} \bar{l}_R/\bar{l}_B & \bar{l}_G/\bar{l}_B & 1 \\ \bar{m}_R/\bar{m}_B & \bar{m}_G/\bar{m}_B & 1 \\ 0 & \bar{s}_G/\bar{s}_B & 1 \end{pmatrix} \begin{pmatrix} \bar{r}(\lambda) \\ \bar{g}(\lambda) \\ \bar{b}(\lambda) \end{pmatrix} = \begin{pmatrix} k_l \bar{l}(\lambda) \\ k_m \bar{m}(\lambda) \\ k_s \bar{s}(\lambda) \end{pmatrix}, \quad (3)$$

where the absolute values of k_l (or $1/\bar{l}_B$), k_m (or $1/\bar{m}_B$), and k_s (or $1/\bar{s}_B$) remain unknown, but are typically chosen to scale three functions in some way, for example, so that $k_l \bar{l}(\lambda)$, $k_m \bar{m}(\lambda)$, and $k_s \bar{s}(\lambda)$ peak at unity.

L- and M-cone Fundamentals

The four M- and L-cone unknowns in Eq. 3, $\bar{l}_R/\bar{l}_B$, $\bar{l}_G/\bar{l}_B$, $\bar{m}_R/\bar{m}_B$, and $\bar{m}_G/\bar{m}_B$, can be estimated by fitting CMFs to the cone spectral sensitivity data shown in Fig. 2. However, since the cone spectral sensitivity data are defined for 2-deg viewing conditions and the CMFs for 10-deg, we employed an intermediate step of fitting the 2-deg data to the Stiles and Burch [8] 2-deg CMFs. Figure 2 shows the linear combinations of the Stiles and Burch 2-deg CMFs that best fit the mean L(ser^{180}) deuteranope data (red circles), L(ala^{180}) deuteranope data (yellow and orange squares), and L1M2/L2M3 protanope data (green diamonds) of Sharpe et al. [11]. An overall population mean for the L-cone spectral sensitivity function was derived by averaging the L(ser^{180}) and L(ala^{180}) fits after weighting them in ratio of 62 L(ser^{180}) to 38 L(ala^{180}), which is the ratio believed to correspond to normal population incidences (see Table 1 of Reference 2).

Having defined the mean L- and M-cone fundamentals in terms of the 2-deg Stiles and Burch CMFs, they were next defined in terms of linear combinations of the Stiles and Burch [3] 10-deg CMFs corrected to 2-deg. These were derived by a curve-fitting procedure in which the linear combinations of the Stiles and Burch 10-deg CMFs found that, after adjustment to 2-deg macular, lens and photopigment densities best fit the Stiles and Burch-based 2-deg L- and M-cone fundamentals. The coefficients are given in Eq. 4.

In one final refinement, the relative weights of the blue CMF were fine-tuned for consistency with tritanopic color matching data [13], from which the S-cones are excluded (for further details, see [2]). This final adjustment is important because of the inevitable uncertainties that arise at short wavelengths owing to individual differences in preretinal filtering.

S-Cone Fundamental

The coefficients for the transformation to the S-cone fundamental require knowledge of just one unknown, $\bar{s}_G/\bar{s}_B$, which can similarly be estimated by fitting CMFs to the cone spectral

sensitivity data. The upper panel of Fig. 3 shows the mean central S-cone spectral sensitivities (blue circles) measured by Stockman, Sharpe, and Fach [12] averaged from normal and blue-cone monochromat data below 540 nm and from blue-cone monochromat data alone from 540 to 615 nm. Superimposed on the threshold data is the linear combination of the Stiles and Burch 2-deg $\bar{b}(\lambda)$ and $\bar{g}(\lambda)$ CMFs that best fits the data below 565 nm with best-fitting adjustments to the lens and macular pigment densities.

The unknown value, $\bar{s}_G/\bar{s}_B$, can also be derived directly from the color matching data [14]. This derivation depends on the longer-wavelength part of the visible spectrum being tritanopic for lights of the radiances typically used in color matching experiments. Thus, target wavelengths longer than about 560 nm, as well as the red primary, are invisible to the S-cones. In contrast, the green and blue primaries are both visible to the S-cones. Targets longer than 560 nm can be matched for the L- and M-cones by a mixture of the red and green primaries, but a small color difference typically remains, because the S-cones detect the field containing the green primary. To complete the match for the S-cones, a small amount of blue primary must be added to the field opposite the green primary. The sole purpose of the blue primary is to balance the effect of the green primary on the S-cones. Thus, the ratio of green to blue primary should be negative and fixed at $\bar{s}_G/\bar{s}_B$, the ratio of the S-cone spectral sensitivity to the two primaries.

The lower left panel of Fig. 3 shows the Stiles and Burch [8] green, $g(\lambda)$, and blue, $b(\lambda)$, 2-deg chromaticity coordinates (blue squares). As expected, the function above ~555 nm is a straight line. It has a slope of -0.01625 , which implies $\bar{s}_G/\bar{s}_B = 0.01625$, and is the same as the value obtained from the direct spectral sensitivity measurements, 0.0163 (upper panel). The lower right panel of Fig. 3 shows the Stiles and Burch [3] green, $g(\lambda)$, and blue, $b(\lambda)$, 10-deg chromaticity coordinates and the line that best fits the data above 555 nm, which has a slope of -0.0106 (light blue diamonds). Thus, the color matching data suggest that $\bar{b}(\lambda) + 0.0106 \bar{g}(\lambda)$ is the S-cone fundamental in the Stiles and Burch [3] 10-deg space. The differences between the 2-deg

(left panel) and 10-deg (right panel) coefficients are consistent with changes in preretinal filtering and in photopigment optical density with eccentricity.

LMS Transformation Matrix

The transformation matrix from the Stiles and Burch [3] 10-deg $\bar{r}_{10}(\lambda)$, $\bar{g}_{10}(\lambda)$, and $\bar{b}_{10}(\lambda)$ CMFs to the three cone fundamentals, $\bar{l}_{10}(\lambda)$, $\bar{m}_{10}(\lambda)$, and $\bar{s}_{10}(\lambda)$ CMFs, is given by Eq. 4:

$$\begin{aligned}\bar{l}_{10}(\lambda) &= 2.846201 \bar{r}_{10}(\lambda) + 11.092490 \bar{m}_{10}(\lambda) \\ &\quad + \bar{b}_{10}(\lambda), \\ \bar{m}_{10}(\lambda) &= 0.168926 \bar{r}_{10}(\lambda) + 8.265895 \bar{g}_{10}(\lambda) \\ &\quad + \bar{b}_{10}(\lambda), \\ \bar{s}_{10}(\lambda) &= 0.010600 \bar{g}_{10}(\lambda) + \bar{b}_{10}(\lambda).\end{aligned}\quad (4)$$

The S-cone fundamental at wavelengths longer than 520 nm does not depend upon this transformation, but is based instead on the blue-cone monochromat spectral sensitivity measurements.

The 2-deg cone fundamentals are the 10-deg functions adjusted in photopigment optical density and macular pigment density according to the expected differences in those densities for 2-deg and 10-deg viewing conditions. Because the CMFs are conventionally given in energy units, this transformation yields cone fundamentals in energy units. To convert cone fundamentals in energy units to quantal units, which are more practical for vision science, multiply by λ^{-1} . The values of k_l , k_m , and k_s in Eq. 3 depend on the desired normalization and on the units (energy or quanta). For further details, see [2]. Tabulated functions can be downloaded from <http://www.cvrl.org>.

XYZ Transformation Matrix

By making a few simple assumptions, the cone fundamental CMFs, $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$, can be linearly transformed to the more familiar

colorimetric variants: $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, a form still in common use.

First, the $\bar{y}(\lambda)$ CMF is assumed to be the 2-deg or 10-deg version of the luminous efficiency functions proposed by Sharpe et al. [15], which are linear combinations of $\bar{l}(\lambda)$ and $\bar{m}(\lambda)$ (defined in Eqs. 5 and 6, below). Second, the $\bar{z}(\lambda)$ CMF is assumed to be the $\bar{s}(\lambda)$ cone fundamental scaled to have an equal integral to the $\bar{y}(\lambda)$ CMF for an equal energy white. Lastly, the definition of the $\bar{x}(\lambda)$ CMF, which owes much to the efforts of Jan Henrik Wold for the TC 1–36 committee, is based on a series of requirements: (i) like the other CMFs, the values of $\bar{x}(\lambda)$ are all positive; (ii) the integral of $\bar{x}(\lambda)$ for an equal energy white is identical to the integrals for $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$; and (iii) the coefficients of the transformation that yields $\bar{x}(\lambda)$ are optimized to minimize the Euclidian differences between the resulting $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ chromaticity coordinates and the CIE 1931 $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ chromaticity coordinates.

The 2-deg transformation is given by Eq. 5:

$$\begin{aligned}\bar{x}(\lambda) &= 1.94735469 \bar{l}(\lambda) - 1.41445123 \bar{m}(\lambda) \\ &\quad + 0.36476327 \bar{s}(\lambda), \\ \bar{y}(\lambda) &= 0.68990272 \bar{l}(\lambda) + 0.34832189 \bar{m}(\lambda), \\ \bar{z}(\lambda) &= 1.93485343 \bar{s}(\lambda),\end{aligned}\quad (5)$$

where $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$ are the CIE 2-deg cone fundamentals of Stockman and Sharpe [2].

The 10-deg transformation is given by Eq. 6:

$$\begin{aligned}\bar{x}_{10}(\lambda) &= 1.93986443 \bar{l}_{10}(\lambda) - 1.34664359 \bar{m}_{10}(\lambda) \\ &\quad + 0.43044935 \bar{s}_{10}(\lambda), \\ \bar{y}_{10}(\lambda) &= 0.69283932 \bar{l}_{10}(\lambda) + 0.34967567 \bar{m}_{10}(\lambda), \\ \bar{z}_{10}(\lambda) &= 2.14687945 \bar{s}_{10}(\lambda),\end{aligned}\quad (6)$$

where $\bar{l}_{10}(\lambda)$, $\bar{m}_{10}(\lambda)$, and $\bar{s}_{10}(\lambda)$ are the CIE 10-deg cone fundamentals of Stockman and Sharpe [2]. Tabulated functions can be downloaded from <http://www.cvrl.org>.

When plotted as 2-deg chromaticity coordinates, $x(\lambda)$ and $y(\lambda)$, where:

CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams, Fig. 4 CIE physiologically relevant 2-deg x, y chromaticity space showing the spectrum locus (continuous line) and spectral wavelengths at every 10 nm (filled circles). An approximate representation of the color of each coordinate is shown

$$x(\lambda) = \frac{\bar{x}(\lambda)}{\bar{x}(\lambda) + \bar{y}(\lambda) + \bar{z}(\lambda)} \quad (7)$$

- Protanopia
- Spectral luminous Efficiency
- Trichromacy

and

$$y(\lambda) = \frac{\bar{y}(\lambda)}{\bar{x}(\lambda) + \bar{y}(\lambda) + \bar{z}(\lambda)},$$

the spectrum locus and chromaticity diagram, shown in Fig. 4, have the familiar appearance of the 1931 CIE x, y chromaticity diagram.

CIE Special Metamerism Index: Change in Observer

Abhijit Sarkar
Mixed Reality Systems Engineering, Microsoft
Corporation, Redmond, WA, USA

Synonyms

[CIE Standard Deviate Observer](#)

Definition

Special Metamerism Index: Change in observer refers to a method for evaluating the average of

and the range of color mismatches for metameric color pairs when test observers with normal color vision are substituted for a reference observer (i.e., a CIE standard colorimetric observer). This method was proposed in 1989 by the CIE Technical Committee 1-07 [1]. The method, principally based on the works of Nayatani et al. [2] and Takahama et al. [3], was intended to evaluate both the average values and the range of color mismatches.

Overview

Two color stimuli with different spectral characteristics within the visible spectral range can have identical tristimulus values for a given illuminant and the reference observer (standard colorimetric observer). These stimuli are said to be metameric. Such metameric color match breaks down on changing the illuminant (illuminant metamerism) or the observer (observer metamerism). This is depicted in Fig. 1. While for observer A (reference observer), spectra 1 and spectra 2 (shaded curves) result in identical tristimulus values, they are no longer identical in the case of observer B (test observer), since this observer's color-matching functions differ from those of observer A. If the spectral characteristics of the primary colorants of two-color reproduction devices are not the same, any color match made on these devices is metameric in nature and thus may not hold when one observer is replaced by another.

Given the fact that the concept of metamerism is fundamentally important in the science of colorimetry, it was recognized long ago that a suitable index to quantify this effect would be of high relevance. It is relatively straightforward to formulate specific indices for illuminant metamerism, based on the color differences of a metameric pair under various sources of illumination. However, it is quite challenging to define a general index for observer metamerism. This is due to the immense variability that exists in the spectral sensitivities of the cone photoreceptors of individual observers having normal color vision. This variability is manifested in the measured color-matching functions and thus in color

CIE Special Metamerism Index: Change in Observer, Fig. 1 A graphical depiction of the phenomenon of observer metamerism. For observer A (the reference observer), the tristimulus values resulting from spectrally integrating the color-matching functions of observer A and

the two spectra are identical. However, that is no longer the case for observer B, whose color-matching functions are different from those of observer A. Thus, spectra 1 and 2 are metameric. (Image courtesy: Dr. Laurent Blondé)

mismatches in a metameric pair when evaluated by individual observers.

Observer metamerism can be evaluated using experimental procedure involving actual observers with normal color vision or through mathematical modeling, using a set of color-matching functions that is representative of individual variations among color-normal observers. In one of the first attempts to model the uncertainties involved in the color-matching data, Nimeroff et al. [4] proposed a statistical model they termed as complete standard colorimetric observer system. The model included the mean of the color-matching functions of various observers as well as variance and covariance of these functions derived from the intra- and interobserver variability. On the other hand, Wyszecki and Stiles [5] attempted to define an index for observer metamerism by using the color-matching functions of 20 individual observers from the large-field color-matching

experiment of Stiles and Burch [6]. They computed color differences for a given metameric pair as perceived by each of the 20 observers and used the mean color difference as the degree of observer metamerism. However, this method was not proposed with industrial applications in mind.

In 1989, a method was formulated by the CIE for evaluating observer metamerism. The method was detailed in a technical report titled “CIE Special Metamerism Index: Change in Observer,” prepared by the CIE Technical Committee (TC) 1-07. The committee came under CIE Division 1 (Vision and Color) and was chaired by Professor N. Ohta. This method was analogous to the one for evaluating illuminant metamerism, proposed by the CIE in 1986: “Special Metamerism Index: Change in Illuminant” [7]. This method, described hereafter as CIE observer metamerism index, assessed the degree of color mismatch for metameric color pairs (object colors

or illuminant colors), resulting from substitution of the reference observer by a test observer. The reference observer is either the CIE 1931 standard colorimetric observer or the CIE 1964 supplementary standard colorimetric observer. The test observers are assumed to be a number of actual observers with normal color vision and are represented by four deviation functions characterizing the variations of color-matching functions of color-normal observers.

Standard Deviate Observer

Computation of the CIE observer metamerism index requires the use of color-matching functions for a standard deviate observer. Thus, the definition of the standard deviate observer and an overview of various propositions for its formulation would be relevant here.

The concept of standard deviate observer is a mathematical construct that was first proposed by Allen in 1970 [8]. This observer has color-matching functions differing from the reference observer by amounts equal to standard deviations among a defined set of color-normal observers. Allen and subsequently other researchers used the 20 individual Stiles and Burch observers [6] for deriving the standard deviate observer.

In the method proposed by Allen [8], starting from the standard deviations $\Delta\bar{x}(\lambda)$, $\Delta\bar{y}(\lambda)$, and $\Delta\bar{z}(\lambda)$ of color-matching functions of the 20 Stiles and Burch observers, differential tristimulus values ΔX , ΔY , and ΔZ were computed for any metameric pair. These values represented the root mean square differences in tristimulus values for a metameric pair as perceived by the observers. The tristimulus and delta tristimulus values could then be used in a color-difference formula to calculate ΔE , which was the desired observer metamerism index. Allen's method allowed for negative differences in tristimulus values.

In a different statistical approach, Nayatani et al. [9] performed a singular value decomposition analysis on the 20-observer data and derived three deviation functions whose linear combinations were used to reconstitute the color-matching

functions of the 20 Stiles and Burch observers. Further, the authors showed that the first deviation function was similar to Allen's standard deviate observer. Adding the first deviation function to the reference observer (e.g., CIE 1964 supplementary standard colorimetric observer) yielded the test observer. Observer metamerism indices derived by using the first deviation function showed high correlation to the average metamerism index of the 20 Stiles and Burch observers. These results were obtained by using two sets of metameric spectral reflectance values of 12 and 68 metamers.

A subsequent study by Takahama et al. [3] expanded the method by using the first deviation to evaluate the index of observer metamerism. All four deviation functions were used to construct the confidence ellipsoids of tristimulus values defining the range of mismatches expected for a given pair of metamers, viewed by actual observers with normal color vision but different from the reference.

In an independent study, Ohta [10] performed a nonlinear optimization of the 20-observer data to formulate a standard deviate observer model. The model was close to the one obtained by Nayatani [9] and was assessed to well represent the original 20 observers.

Procedure for Computing CIE Observer Metamerism Index

Tristimulus values for a pair of object colors metameric for a reference observer with color-matching functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ and an illuminant with spectral power distribution $S(\lambda)$ are given by Eq. 1.

$$\begin{bmatrix} X_{ref,i} \\ Y_{ref,i} \\ Z_{ref,i} \end{bmatrix} = \sum_{\lambda} \rho_i(\lambda) S(\lambda) \begin{bmatrix} \bar{x}(\lambda) \\ \bar{y}(\lambda) \\ \bar{z}(\lambda) \end{bmatrix} \Delta\lambda \quad (1)$$

where $\rho_i(\lambda)$ is the spectral reflectance of the i -th object color ($i = 1, 2$) of the metameric pair.

Since the object colors are metameric, this can be written as:

$$\begin{aligned} X_{ref,1} &= X_{ref,2} \cong X_{ref} \\ Y_{ref,1} &= Y_{ref,2} \cong Y_{ref} \\ Z_{ref,1} &= Z_{ref,2} \cong Z_{ref} \end{aligned} \quad (2)$$

Further, $S(\lambda)$ is normalized so that it has a luminance of 100, as shown in Eq. 3.

$$\sum_{\lambda} S(\lambda) \bar{y}(\lambda) \Delta\lambda = 100 \quad (3)$$

Four sets of deviation functions $\bar{x}_j(\lambda)$, $\bar{y}_j(\lambda)$, and $\bar{z}_j(\lambda)$, where j denotes the set number, are used in this method and have been tabulated in the report of CIE TC 1-07.

The first set of deviation functions denotes the differences in color-matching functions of CIE standard colorimetric observer and the standard deviate observer [denoted by $\bar{x}_{dev}(\lambda)$, $\bar{y}_{dev}(\lambda)$, and $\bar{z}_{dev}(\lambda)$]. Thus, the color-matching functions of the standard deviate observer are obtained by using Eq. 4.

$$\begin{aligned} \bar{x}_{dev}(\lambda) &= \bar{x}(\lambda) + \Delta\bar{x}_1(\lambda) \\ \bar{y}_{dev}(\lambda) &= \bar{y}(\lambda) + \Delta\bar{y}_1(\lambda) \\ \bar{z}_{dev}(\lambda) &= \bar{z}(\lambda) + \Delta\bar{z}_1(\lambda) \end{aligned} \quad (4)$$

From these color-matching functions, the tristimulus values $X_{dev,i}$, $Y_{dev,i}$, and $Z_{dev,i}$ of metameric object colors ($i = 1$ or 2) corresponding to the standard deviate observer can be obtained as shown in Eq. 5.

$$\begin{bmatrix} X_{dev,i} \\ Y_{dev,i} \\ Z_{dev,i} \end{bmatrix} = \sum_{\lambda} \rho_i(\lambda) S(\lambda) \begin{bmatrix} \bar{x}_{dev}(\lambda) \\ \bar{y}_{dev}(\lambda) \\ \bar{z}_{dev}(\lambda) \end{bmatrix} \Delta\lambda \quad (5)$$

The CIE observer metamerism index (M_{obs}) for the pair of metameric object colors is expressed by Eq. 6.

$$M_{obs} = \Delta E_{obs}^* \left[(X_{dev,1}, Y_{dev,1}, Z_{dev,1}), (X_{dev,2}, Y_{dev,2}, Z_{dev,2}) \right] \quad (6)$$

where ΔE_{obs}^* is the color difference between the metameric object colors as evaluated by the standard deviate observer, calculated in a uniform

color space. CIE TC 1-07 recommends CIE 1976 (L^* , u^* , v^*) or (L^* , a^* , b^*) as uniform color space [7].

When the tristimulus values of the samples do not exactly match, they are not strictly metameric (instead, they are parameric). In such a scenario, the tristimulus values of the first stimulus are defined as reference (X_{ref} , Y_{ref} , and Z_{ref}), as in Eq. 7.

$$\begin{aligned} X_{ref} &= X_{ref,1} (\neq X_{ref,2}) \\ Y_{ref} &= Y_{ref,1} (\neq Y_{ref,2}) \\ Z_{ref} &= Z_{ref,1} (\neq Z_{ref,2}) \end{aligned} \quad (7)$$

The tristimulus values of the second stimulus obtained by Eq. 5 are then corrected using Eq. 8.

$$\begin{aligned} X'_{dev,2} &= X_{dev,2} \left(\frac{X_{ref,1}}{X_{ref,2}} \right) \\ Y'_{dev,2} &= Y_{dev,2} \left(\frac{Y_{ref,1}}{Y_{ref,2}} \right) \\ Z'_{dev,2} &= Z_{dev,2} \left(\frac{Z_{ref,1}}{Z_{ref,2}} \right) \end{aligned} \quad (8)$$

Deriving 95% Confidence Ellipse

Resultant tristimulus values of metameric colors inevitably mismatch when evaluated by a test observer. These tristimulus values spread within a certain range in the three-dimensional color space. This range is characterized in a chromaticity diagram by a statistical confidence ellipse encompassing 95% of the spread. In this way, evaluation of observer metamerism allows an estimation of tolerances in color-difference judgments for various metameric color pairs.

All four deviate observer functions are used to estimate the confidence ellipse containing 95% of color mismatches. First, a set of tristimulus value deviations for a pair of metameric object colors is defined using Eq. 9.

$$\begin{bmatrix} \Delta^2 X_j \\ \Delta^2 Y_j \\ \Delta^2 Z_j \end{bmatrix} = \sum_{\lambda} [\rho_2(\lambda) - \rho_1(\lambda)] S(\lambda) \begin{bmatrix} \bar{x}_j(\lambda) \\ \bar{y}_j(\lambda) \\ \bar{z}_j(\lambda) \end{bmatrix} \Delta\lambda \quad (9)$$

Here, the spectral reflectance factors of the object colors are represented by $\rho_1(\lambda)$ and $\rho_2(\lambda)$, and j refers to one of the four deviation functions. As before, the spectral power distribution of the illuminant is denoted by $S(\lambda)$.

In case of metameric illuminant colors, the spectral power distributions $S_1(\lambda)$ and $S_2(\lambda)$ of the illuminant pair are normalized similar to Eq. 3. Instead of Eqs. 9 and 10 is used.

$$\begin{bmatrix} \Delta^2 X_j \\ \Delta^2 Y_j \\ \Delta^2 Z_j \end{bmatrix} = \sum_{\lambda} [S_2(\lambda) - S_1(\lambda)] \begin{bmatrix} \bar{x}_j(\lambda) \\ \bar{y}_j(\lambda) \\ \bar{z}_j(\lambda) \end{bmatrix} \Delta\lambda \quad (10)$$

Next, two matrices D and V are defined as shown in Eqs. 11 and 12.

$$D = \frac{1}{(X_{ref} + 15Y_{ref} + 3Z_{ref})^2} \begin{bmatrix} 60Y_{ref} + 12Z_{ref} & -60X_{ref} & -12X_{ref} \\ -9Y_{ref} & 9X_{ref} + 27Z_{ref} & -27Y_{ref} \end{bmatrix} \quad (11)$$

$$V = \sum_{i=1}^4 \begin{bmatrix} (\Delta^2 X_i)^2 & \Delta^2 X_i \cdot \Delta^2 Y_i & \Delta^2 Z_i \cdot \Delta^2 X_i \\ \Delta^2 X_i \cdot \Delta^2 Y_i & (\Delta^2 Y_i)^2 & \Delta^2 Y_i \cdot \Delta^2 Z_i \\ \Delta^2 Z_i \cdot \Delta^2 X_i & \Delta^2 Y_i \cdot \Delta^2 Z_i & (\Delta^2 Z_i)^2 \end{bmatrix} \quad (12)$$

The variance-covariance matrix Σ of the (u', v') chromaticity coordinates of all the color matches evaluated by test observers is given by Eq. 13.

$$\Sigma = DVD^t \quad (13)$$

where D^t is the transpose of matrix D . If the elements of inverse matrix Σ^{-1} are denoted as Σ_{mn} where m is the row and n is the column of a given element, the confidence ellipse containing 95% of the color mismatches is given by Eq. 14.

$$\begin{aligned} & \sum^{11} (\Delta u')^2 + 2 \sum^{12} (\Delta u') (\Delta v') \\ & + \sum^{22} (\Delta v')^2 \\ & = \chi^2(2, 0.05) = 5.991 \end{aligned} \quad (14)$$

Here, $\chi^2(2, 0.05)$ is the 5% of the χ^2 distribution for two degrees of freedom.

The center of the ellipse is given by (u_{ref}, v_{ref}) , which corresponds to the reference observer.

It should be noted that the two-dimensional ellipse in the chromaticity diagram does not contain information about the psychometric lightness of the stimuli. Thus, the ellipse cannot be used for comparing the degree of observer metamerism between two different metameric pairs with varying lightness.

Effect of Age on Color Mismatches

The CIE TC 1-07 report [1] also proposes a method that accounts for the effect of age on the index of observer metamerism. Mainly, aging of the lens (pigmentation) is considered as a contributing factor. A pair of object colors which are metameric for an average observer with an age N_1 and a reference illuminant will mismatch for an observer with an age N_2 . The deviation functions $\Delta\bar{x}_1(\lambda, N)$, $\Delta\bar{y}_1(\lambda, N)$, and $\Delta\bar{z}_1(\lambda, N)$ for age N ($20 \leq N \leq 60$) are computed using Eqs. 15 and 16. These values are used instead of those obtained from Eq. 4.

$$\begin{bmatrix} \Delta\bar{x}_1(\lambda, N) \\ \Delta\bar{y}_1(\lambda, N) \\ \Delta\bar{z}_1(\lambda, N) \end{bmatrix} = L(N) \cdot \begin{bmatrix} \Delta\bar{x}_1(\lambda) \\ \Delta\bar{y}_1(\lambda) \\ \Delta\bar{z}_1(\lambda) \end{bmatrix} \quad (15)$$

$$L(N) = 0.064 \cdot N - 2.31 \quad (16)$$

Evaluation of the CIE Observer Metamerism Index

Following the introduction of CIE observer metamerism index [1], several researchers evaluated the model with independent experimental data. North and Fairchild [11] conducted a Maxwell-type color-matching experiment using a cathode ray tube (CRT) display and a tungsten-halogen lamp on two halves of a 2° bipartite field. The authors estimated the color-matching functions of each observer through a mathematical model, starting from experimental data obtained at seven wavelengths. They concluded that the interobserver variability in the experimental data was much larger than what was predicted by the CIE model [1].

Alfvin and Fairchild [12] conducted another visual experiment on color matches between color prints or transparencies and a CRT display. They used an equilateral glass prism to allow the observers to view simultaneously both the soft and hard copy stimuli in a vertically symmetric bipartite field. In analyzing the data, they arrived at the same conclusion: The interobserver variability was significantly larger than the prediction

of the CIE observer metamerism index [1]. As an example, Fig. 2 shows bivariate 95% confidence ellipses containing the range of CIELAB (Δa^* , Δb^*) color mismatches for cyan-transparency sample. The plot includes bivariate ellipse calculated using the CIE method [1] as well as experimentally determined bivariate ellipses for intra- and interobserver color matches. According to these results, the interobserver variability is significantly underpredicted by the CIE observer metamerism index [1].

Oicherman et al. [13] conducted an asymmetric color-matching experiment where 11 observers were asked to match the colors displayed on a CRT and an LCD to the colors of 2 achromatic and 8 chromatic paint samples placed inside a light booth. Even in this study, the authors reported a significant underprediction of the observer variations of color-matching data by the CIE observer metamerism index [1], accounting for only 15% of interobserver variability.

Why did the CIE observer metamerism index not perform well? The suggested explanations include the exclusion of some of the Stiles and Burch observers from the analysis that led to the development of the CIE observer metamerism

CIE Special Metamerism Index: Change in Observer,

Fig. 2 Comparison of 95% confidence regions for measured and predicted ranges of color mismatch for the cyan transparency. Measured data are shown for Alfvin and Fairchild [12] and Nimeroff et al. [4], along with confidence region predicted by the CIE observer metamerism index (CIE standard deviate observer). All data are shown in CIELAB $\Delta a^* - \Delta b^*$ plane. (Reproduced from Alfvin and Fairchild [12])

index [11] and improper mathematical treatment of the original color-matching data [12]. Looking from the point of view of practical industrial applications, in particular hard copy versus soft copy color matching, some researchers [13] have questioned the purpose and usefulness of an index of observer metamerism and a standard deviate observer. They suggested that individual variability in these conditions is governed by mechanisms of chromatic discrimination and could be modeled by advanced color-difference formulas with suitably adjusted parametric coefficients.

Future Directions

In 2006, CIE's Technical Committee 1-36 published a report [14] on the choice of a set of color-matching functions and estimates of cone fundamentals for the color-normal observer. Starting from the 10° color-matching functions of 47 observers from Stiles and Burch's large-field color-matching experiment [6], the model defines 2° and 10° fundamental observers and provides a convenient framework for calculating average cone fundamentals for any field size between 1° and 10° and for an age between 20 and 80. This model provides a theoretical framework for quantifying observer metamerism resulting from age variations. Subsequently, CIE TC 170-1 published guidance [15] to mathematically compute spectral luminous efficiency functions and chromaticity diagrams for physiological observers.

Adopting a different approach to address the issue of observer metamerism in applied colorimetry, Sarkar et al. [16] introduced the concept of colorimetric observer categories. In this work, eight of such categories were derived through statistical analyses of a combined dataset of experimental and physiological color-matching functions. Physiological data were obtained from the mathematical model proposed by CIE TC 1-36 [14], while experimental data consisted of color-matching functions of 47 Stiles and Burch observers [6]. The authors developed and implemented an experimental method to classify

a color-normal human observer as belonging to one of these categories, based on his or her color vision. Subsequently, a compact proof-of-concept prototype for conducting such experiments was developed [17].

As a follow-up to that work, Asano et al. developed a synthetic vision model for individual colorimetric observers [18]. The authors extended the CIE TC 1-36 physiological observer by adding eight additional physiological parameters. Corresponding population variability was defined by standard deviations, which was then used to simulate a large dataset of color-matching functions using Monte Carlo simulation. Subsequently, Asano and Fairchild proposed a set of categorical observer functions [19]. A similar methodology as that of Sarkar et al. [17] was used, but there were a couple of key differences in the approach. While Sarkar et al.'s method relied on measured color-matching functions of Stiles-Burch observers and CIE TC 1-36 model prediction essentially based on the same measured data, Asano and Fairchild's method used synthetic vision model developed earlier by Asano et al. [18]. Further, Sarkar et al. envisioned that a unique set of observer categories could be established using a standardized apparatus based on large field-of-view (10°) color matching. Asano and Fairchild's observer models on the other hand are based entirely on theoretical analysis of the synthetic dataset, to avoid any dependence on the spectral properties of color primaries of any specific device. A set of ten categorical observers was found to be optimal for general use.

At the time of writing this essay, more and more studies are leveraging the concept of observer categories in investigating various aspects of observer metamerism, such as the one by Park et al. [20]. As various researchers continue to validate the usefulness of the concept of observer categories and observer classification in the study of observer metamerism, this can eventually lead to an alternative method for quantifying such metamerism in applied colorimetry as well as for providing a practical solution to the issue of observer metamerism in various color-critical industrial applications.

Definitions

CIE Standard Illuminants

Illuminants A and D65 defined by the CIE in terms of relative spectral power distributions [1].

Note 1: These illuminants are intended to represent:

A: Planckian radiation at a temperature of about 2,856 K

D65: The relative spectral power distribution representing a phase of daylight with a correlated color temperature of approximately 6,500 K (called also “nominal correlated color temperature of the daylight illuminant”)

Note 2: Illuminants B and C and other D illuminants, previously denoted as “standard illuminants,” should now be termed “CIE illuminants.”

CIE Standard Sources

Artificial sources specified by the CIE whose radiation approximate CIE standard illuminants.

Note: CIE sources are artificial sources that represent CIE illuminants.

Overview

As shown already in the section Definitions, one has to distinguish between illuminants and sources: The term “illuminant” refers to a defined spectral power distribution, not necessarily realizable or provided by an artificial source. Illuminants are used in colorimetry to compute the tristimulus values of reflected or transmitted object colors under specified conditions of illumination. The term “source” refers to a physical emitter of light, such as a lamp or the sky.

The CIE colorimetric system was established in 1931 [2], and CIE defined in those days three illuminants: illuminants A, B, and C. Illuminant A was chosen to resemble the spectral power distribution (SPD) of an average incandescent lamp, the SPD of illuminant B was near to that of average direct sunlight, and illuminant C represented average daylight. During the years, it turned out that illuminant B was very seldom used and was soon dropped. Illuminant C was defined only in the visible

spectrum, and with the introduction of optical brighteners, colorimetry needed illuminants with defined ultraviolet radiation content. In 1964 the CIE recommended a new set of daylight illuminants [3], where the SPD was also defined in the ultraviolet (UV) part of the spectrum, and decided that one of these, with a correlated color temperature near to 6,500 K, should be used whenever possible. Thus finally, CIE selected illuminant A and D65 as its standard illuminants, CIE standard illuminant A and CIE standard illuminant D65. The SPD of all illuminants defined by the CIE is available in the Technical Report Colorimetry [4] and the standard on CIE Standard Illuminants for Colorimetry [5].

CIE Standard Illuminant A

Originally CIE standard illuminant A (CIE St. Ill. A) was intended to represent typical, domestic, tungsten-filament lighting. Despite the fact that tungsten incandescent lamp light loses on importance, CIE St. Ill. A is the primary standard for calibrating photometers and colorimeters.

The relative spectral power distribution (SPD) of CIE St. Ill. A, $S_A(\lambda)$, is defined by the equation

$$S_A(\lambda) = 100 \left(\frac{560}{\lambda} \right)^5 \times \frac{\exp \frac{1,435 \times 10^7}{2,848 \times 560} - 1}{\exp \frac{1,435 \times 10^7}{2,848 \lambda} - 1}$$

where λ is the wavelength in nanometers. For practical applications, it is defined also in tabulated form over the wavelength range between 300 nm and 830 nm to six significant digits at 1 nm intervals [5]. The wavelength is to be taken as being in standard air (dry air at 15 °C and 101,325 Pa, containing 0.03% by volume of carbon dioxide). The numerical values in the two exponential terms are defined constants originating from the first definition of illuminant A [5].

CIE Standard Illuminant D65

The most important light source is daylight, the SPD of which changes during the day and depends also on weather conditions, etc.. From detailed measurements [7], the SPD of an often

encountered phase of daylight has been selected as primary reference spectrum. This SPD has a correlated color temperature of approximately 6,504 K and has been termed D65. CIE standardized this SPD as CIE standard illuminant D65 (CIE St. III. D65, or shortly D65); it should represent average daylight SPD. (For further details, see chapter on “Daylight Illuminants.”) For the time being, the relative SPD of CIE St. III. D65 is defined in tabulated form between 300 nm and 830 nm at 1 nm intervals. The wavelength values given apply in standard air. Intermediate values may be derived by linear interpolation.

CIE stated that CIE St. III. D65 should be used in all colorimetric calculations requiring representative daylight, unless there are specific reasons for using a different illuminant.

Short History

CIE Standard Illuminant A

CIE St. III. A was originally defined in 1931 as the relative spectral power distribution of a Planckian radiator of temperature $T = 2,848$ K, where Planck's equation has the form

$$M_{e,\lambda}(\lambda, T) = c_1 \lambda^{-5} [\exp(c_2/\lambda T) - 1]^{-1},$$

where $M_{e,\lambda}$ is radiant exitance (quotient of the radiant flux, $d\Phi_e$, leaving an element of the surface containing the point, by the area, dA , of that element).

In this equation, c_1 is not relevant, as $S_A(\lambda)$ is defined as a relative SPD; the c_2 constant's value was at the time of defining CIE St. III. A 14,350 $\mu\text{m}\cdot\text{K}$. The SPD of CIE St. III. A has not changed since this original definition, only the numerical value of c_2 has been several times reassigned in the International Temperature Scale (ITS), and due to this, the color temperature associated with CIE St. III. A has changed. For the different ITSs, the relevant color temperature values are

$$T_{27} = 2,842 \text{ K}, T_{48} = 2,854 \text{ K},$$

$$T_{68} = T_{90} = 2,856 \text{ K}.$$

Thus, the value we use nowadays is 2,856 K.

Daylight Illuminants

In 1931 CIE defined three reference illuminants, besides CIE St. III. A, also a spectrum that is near to that of direct sunlight, termed illuminant B (but this has been dropped after a short time) and illuminant C, with an SPD in the visible part of the spectrum representing average daylight with a correlated color temperature of approximately 6,774 K [6].

With the introduction of optical brighteners, it became necessary to define the SPD also in the near ultraviolet. The CIE accepted a recommendation by Judd and coworkers [7] to describe phases of daylight [8]. These authors found that although daylight is highly variable, the chromaticities of different phases of daylight fall on a curve more or less parallel to the Planckian locus on the chromaticity diagram. It turned out that the SPDs of the different phases of daylight can be described using only three basic functions, termed $S_0(\lambda)$, $S_1(\lambda)$, and $S_2(\lambda)$; see Fig. 1.

The SPD of a phase of daylight can be calculated using the following equation:

$$S(\lambda) = S_0(\lambda) + M_1 S_1(\lambda) + M_2 S_2(\lambda)$$

where the M_1 and M_2 factors are calculated by the help of the chromaticity coordinates x_D , y_D of the phase of daylight:

$$M_1 = \frac{-1.3515 - 1.7703x_D + 5.9114y_D}{0.0241 + 0.2562x_D - 0.7341y_D},$$

$$M_2 = \frac{0.0300 - 31.4424x_D + 30.0717y_D}{0.0241 + 0.2562x_D - 0.7341y_D}.$$

x_D , y_D are defined by the help of the correlated color temperature (T_{cp}) of the phase of daylight. The x_D coordinate has been defined in two parts for temperatures between 4,000 K and 7,000 K as

$$x_D = \frac{-4.6070 \times 10^9}{(T_{cp})^3} + \frac{2.9678 \times 10^6}{(T_{cp})^2} + \frac{0.09911 \times 10^3}{(T_{cp})} + 0.244063$$

and between 7,000 K and 25,000 K as

CIE Standard Illuminants and Sources,

Fig. 1 Characteristic vectors used to reconstitute phases of daylight

$$x_D = \frac{-2.0064 \times 10^9}{(T_{cp})^3} + \frac{1.9018 \times 10^6}{(T_{cp})^2} + \frac{0.24748 \times 10^3}{(T_{cp})} + 0.237040.$$

With the help of x_D , the corresponding y_D can be calculated as

$$y_D = -3.000 x_D^2 + 2.870 x_D - 0.275.$$

Using above equations, SPDs for any phase of daylight that has a T_{cp} between 4,000 K and 25,000 K can be calculated. From these spectra that corresponding to a T_{cp} of 6,500 was selected as primary standard: D65. As discussed already in connection with CIE St. Ill. A, the International Temperature Scale was based on a different value of the c_2 constant as used today. Thus, to keep the SPD of the D65 unchanged, the correlated color temperature had to be changed. To get to the correct spectrum, one has to insert in above equations the value of 6,504 instead of 6,500. (To be quite precise, the value should be 6503,616134, but for all practical purposes, 6,504 is accurate enough.) Equations have been elaborated that will produce the correct spectra for the rounded value of 6,500 K, and for that, the term “nominal correlated color temperature” is used.

Often SPDs are needed with slightly lower or higher T_{cp} s, thus, e.g., in graphic arts to get daylight spectra nearer to spectra used in indoor applications, a phase of daylight of $T_{cp} = 5,003$ K is used, termed D5000. Besides this, CIE publications often refer to D55 and D75 illuminants as well with T_{cp} of 5,503 and 7,504, respectively.

As can be seen from Fig. 1, the S functions are not smooth functions. Originally their values have been determined at 10 nm intervals and linear interpolation was suggested between these fixed points. A recent CIE recommendation deals with two possible smoothing algorithms, one that keeps the value of the SPD at the fixed points constant [9] and one that smoothes the curves further, so that they can be realized more accurately with physical sources [10, 11]. For further details, see entry on ► “Daylight Illuminants”.

Further CIE Illuminants

Often it is necessary to perform a colorimetric calculation using light source spectra of commercial lamps. To make such calculations more transparent, CIE published the spectra of some commercial gas-discharge lamps [4]: The collection of fluorescent lamp spectra includes 12 older constructions (six halophosphate, three broadband, and three narrowband lamp spectra); a second series contains, besides halophosphate lamps

(three spectra), three Deluxe lamp spectra, five three-band lamp spectra, three multiband spectra, and a D65 simulator spectrum. Further spectra show typical high-pressure sodium lamp and high-pressure metal halide lamp spectra.

CIE Standard Source

The spectrum of coiled coil tungsten incandescent lamps is very near to the SPD of a black-body radiator; thus, CIE standard illuminant A can be realized by a gas-filled tungsten-filament lamp operating at a correlated color temperature of 2,856 K ($c_2 = 14,388 \times 10^{-2} \text{ m} \cdot \text{K}$). If the source is also to be used in the UV region, a lamp having an envelope or window made of fused quartz or silica must be used because glass absorbs the UV component of the radiation from the filament.

The spectrum of CIE standard illuminant D65 is too complicated to be realized with small enough error to represent a standard D65 source. Real sources to be used in visual observations as daylight sources are called “simulators,” and readers are directed to the entry ► “[CIE Method of Assessing Daylight Simulators](#)” for further details.

Definition

Tristimulus values are defined as the amounts of the 3 reference color stimuli, in a given trichromatic system, required to match the color of the stimulus considered.

Background

The International Commission on Illumination (CIE) recommended CIE color specification system as the basis for colorimetry [1]. The ISO and CIE are also provided a series of joint standards [2–4]. The fundamental of colorimetry is Tristimulus Values [4]. They are used for color communication and reproduction. The three key elements of color perception are: human vision system, light, and object. If missing one of three elements, we will not be able to perceive color. These elements have been defined by CIE as color matching functions of $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, or $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, and $\bar{z}_{10}(\lambda)$ for 2° and 10° fields of viewing respectively, across visual spectrum to represent the human population having normal color vision. They also known as CIE 1931 and 1964 standard colorimetric observers (see [2]). CIE also standardized some illuminants in terms of Spectral Power Distribution (SPD) ($S(\lambda)$) [3]. Additionally, CIE specified the illuminating and viewing geometry for measuring a reflecting surface. Each surface is defined by spectral reflectance, $R(\lambda)$, a ratio of the reflected light from a sample to that reflected by a perfect diffuser identically illuminated [1]. The typical instrument for measuring spectral reflectance is a spectrophotometer.

Thus any color can be specified by a triad of numbers called Tristimulus Values, or XYZ values (see Eq. 1). The details can be found in references [1, 4]. An easier explanation can be a color is matched by the amounts of standard red, green, and blue lights by a normal color vision observer under a particular standard illuminant. These are the integration of the products of the functions in three components over the visible spectrum, say 380 to 700 nm.

$$\begin{aligned} X &= k \int_{\lambda} S(\lambda) R(\lambda) \bar{x}(\lambda) d\lambda \\ Y &= k \int_{\lambda} S(\lambda) R(\lambda) \bar{y}(\lambda) d\lambda \\ Z &= k \int_{\lambda} S(\lambda) R(\lambda) \bar{z}(\lambda) d\lambda \end{aligned} \quad (1)$$

where k constant was chosen so that $Y = 100$ for the perfect reflecting diffuser. If the CIE1964 standard colorimetric observer is used in Eqs. 1 and 2 all terms except k , $S(\lambda)$ and $R(\lambda)$ should include a subscript of 10.

For measuring self-luminous colors such as color displays, TV, light sources, Eq. 2 should be used instead of Eq. 1. This is due to the fact that the object and illuminant are not defined. The P function represents the spectral radiance or spectral irradiance of the target stimulus. The areas of colors considered in display applications usually have quite small angular subtense and the CIE 1931 standard colorimetric observer is the appropriate one to use. The typical instrument for measuring spectral radiance or irradiance is a spectroradiometer.

$$\begin{aligned} X &= k \int_{\lambda} P(\lambda) \bar{x}(\lambda) d\lambda \\ Y &= k \int_{\lambda} P(\lambda) \bar{y}(\lambda) d\lambda \\ Z &= k \int_{\lambda} P(\lambda) \bar{z}(\lambda) d\lambda \end{aligned} \quad (2)$$

where k constant is chosen so that $Y = 100$ for the appropriate reference white.

CIE 1976 $L^*u^*v^*$ color space; UCS diagram; Uniform chromaticity scale diagram

Definitions

Uniform Chromaticity Scale Diagram (UCS Diagram)

The CIE 1976 uniform chromaticity scale diagram is a projective transformation of the CIE x , y chromaticity diagram yielding perceptually more uniform color spacing (see CIE colorimetry standard [1]). It is produced by plotting, as abscissa and ordinate, respectively, quantities defined by the equations:

$$u' = \frac{4X}{X + 15Y + 3Z} \quad (1)$$

$$v' = \frac{9Y}{X + 15Y + 3Z} \quad (2)$$

where X , Y , Z are the tristimulus values of the test color stimulus based on the CIE 1931 standard colorimetric system defined in ISO 11664-1/CIE S 014-1 [2].

Equivalent definition:

Uniform Color Space

The CIE 1976 $L^*u^*v^*$ color space is a three-dimensional, approximately uniform color space produced by plotting in rectangular coordinates, L^* , u^* , v^* , quantities defined by the equations

$$L^* = 116 f\left(\frac{Y}{Y_n}\right) - 116 \quad (6)$$

$$u^* = 13 L^* (u' - u'_n) \quad (7)$$

$$v^* = 13 L^* (v' - v'_n) \quad (8)$$

where

$$f\left(\frac{Y}{Y_n}\right) = \left(\frac{Y}{Y_n}\right)^{1/3} \quad \text{if} \quad \frac{Y}{Y_n} > \left(\frac{6}{29}\right)^3 \quad (9)$$

$$f\left(\frac{Y}{Y_n}\right) = \frac{841}{108} \left(\frac{Y}{Y_n}\right) + \frac{4}{29} \quad \text{if} \quad \frac{Y}{Y_n} \leq \left(\frac{6}{29}\right)^3. \quad (10)$$

In these equations, Y , u' , and v' describe the test color stimulus, and Y_n , u'_n , and v'_n describe a specified white stimulus.

If the angle subtended at the eye by the test stimulus is between about 1° and 4° , the tristimulus values X , Y , Z calculated using the color-matching functions of the CIE 1931 standard colorimetric system should be used. If this angular subtense is greater than 4° , the tristimulus values X_{10} , Y_{10} , Z_{10} calculated using the color-matching functions of the CIE 1964 standard colorimetric system should be used. The same color-matching functions and the same specified white stimulus should be used for all stimuli to be compared with each other.

Correlates of Lightness, Saturation, Chroma, and Hue

Approximate correlates of the perceived attributes lightness, saturation, chroma, and hue are calculated as follows:

CIE 1976 lightness	L^* as defined by Eq. 6
CIE 1976 u, v saturation (CIELUV saturation)	$s_{uv} = 13 \left[(u' - u'_n)^2 + (v' - v'_n)^2 \right]^{1/2}$
CIE 1976 u, v chroma (CIELUV chroma)	$C_{uv}^* = \left[(u^*)^2 + (v^*)^2 \right]^{1/2}$
CIE 1976 u, v hue angle (CIELUV hue angle)	$h_{uv} = \arctan (v^*/u^*)$

where the CIELUV hue angle lies between 0° and 90° if u^* and v^* are both positive, between 90° and 180° if v^* is positive and u^* is negative, between 180° and 270° if v^* and u^* are both negative, and between 270° and 360° if v^* is negative and u^* is positive.

Color Differences

The CIE 1976 $L^*u^*v^*$ color difference, ΔE_{uv}^* , between two color stimuli is calculated as the Euclidean distance between the points representing them in the space:

$$\Delta E_{uv}^* = \left[(\Delta L^*)^2 + (\Delta u^*)^2 + (\Delta v^*)^2 \right]^{1/2}$$

$$\text{or } \Delta E_{uv}^* = \left[(\Delta L^*)^2 + (\Delta C_{uv}^*)^2 + (\Delta H_{uv}^*)^2 \right]^{1/2} \quad (11)$$

$$\text{where } \Delta H_{uv}^* = 2 \left(C_{uv,1}^* C_{uv,2}^* \right)^{1/2} \sin(\Delta h_{uv}/2).$$

For further details and calculating differences of color coordinate components, see Eq. 1.

Overview

The CIE 1976 uniform chromaticity scale diagram and the CIE 1976 $L^*u^*v^*$ color space have

been agreed by the CIE in 1976 as a modification of the CIE1960 UCS diagram (u, v diagram) and CIE 1964 uniform color space (U^*, V^*, W^* space). The u, v diagram was devised by David MacAdam [3] and recommended by the CIE in 1959 [4]. Observations have shown that the u, v diagram could be made more uniform if v coordinate would be modified. The original equations for u, v are given in Eq. 12.

$$u = 4X/(X + 15Y + 3Z) \text{ and}$$

$$v = 6Y/(X + 15Y + 3Z);$$

thus, $u' = u$, and $v' = 3v/2$ [5].

Figure 1 shows MacAdam ellipses in the u', v' diagram. As can be seen, the u', v' diagram is not absolutely equidistant (the ellipses are not circles), but its uniformity is by an order of magnitude better as that of the x, y diagram.

The u, v diagram described only chromaticities of colors of equal luminance. In 1963, CIE extended this to a three-dimensional spacing perceptually more nearly uniform than that provided by the (XYZ) system. “The recommended coordinate system is formed by plotting the variables U, V , and W along orthogonal axes where U, V , and W are defined in terms of the tristimulus values X, Y, Z , as

$$W = 25Y^{1/3} - 17, 1 \leq Y \leq 100;$$

$$U = 13W(u - u_n); \quad V = 13W(v - v_n)$$

where u, v, u_n , and v_n are described in the previous paragraphs [6].

The establishment of the CIE uniform chromaticity scale diagram and the CIELUV space was the result of a long-lasting development. The experts, at the CIE 1976 meeting, proposed two systems, the CIELUV and the CIELAB systems, but on the then available visual data, they were unable to decide between the two. During the past 30–40 years, the CIELAB system and its derivatives (see CIELAB in this volume) proved to be a better approximation of color perception; nowadays, the CIELUV space has only very limited use, but the u', v' diagram is still in general use, as it represents a linear diagram, in which chromaticities can easily be calculated. Thus, e.g., if the

CIE u' , v' Uniform Chromaticity Scale Diagram and CIELUV Color Space, Fig. 1 The CIE u' , v' diagram with ten times enlarged MacAdam ellipses (ellipses showing the just noticeable color difference); colors show approximate chromaticity regions in the u' , v' diagram. (From Schubert Light emitting diodes, Chapter 17 Colorimetry, Fig. 17.7, with the kind permission of Cambridge Univ. Pr)

chromaticity of a blue LED and of a phosphor emission that is excited by the LED is given, it is easy to visualize the chromaticities that can be produced by the additive mixture of the two colors; they are located on the straight line drawn between the two chromaticity points.

CIE Whiteness

Stephen Westland
Colour Science and Technology, University of
Leeds, Leeds, UK

Definition

The Commission Internationale de l'éclairage (CIE) whiteness formula was recommended in 1986 as an assessment method for white materials [1]. For the CIE 1931 standard colorimetric observer, the whiteness index W is given by

$$W = Y + 800 (x_n - x) + 1,700 (y_n - y), \quad (1)$$

where x, y are the chromaticity coordinates of the sample, and x_n, y_n are those of the illuminant. For the CIE 1964 supplementary standard colorimetric observer, the whiteness index W_{10} is given by

$$W_{10} = Y + 800 (x_{n,10} - x_{10}) + 1,700 (y_{n,10} - y_{10}), \quad (2)$$

where x_{10}, y_{10} and $x_{n,10}, y_{n,10}$ are the chromaticity coordinates of the sample and the illuminant, respectively.

The tint coefficient T_w or $T_{w,10}$, given by the following formulae, is zero for a sample without reddishness or greenishness. For the CIE 1931 standard colorimetric observer,

$$T_w = 1,000 (x_n - x) - 650 (y_n - y), \quad (3)$$

and for the CIE 1964 supplementary standard colorimetric observer,

$$T_{w,10} = 900 (x_{n,10} - x_{10}) - 650 (y_{n,10} - y_{10}), \quad (4)$$

where x_{10}, y_{10} and $x_{n,10}, y_{n,10}$ are the chromaticity coordinates of the sample and the illuminant, respectively. The tint coefficient allows two samples with the sample whiteness index, W or W_{10} , but with different hue to be distinguished. The more positive the value of T_w or $T_{w,10}$, the greater is the indicated greenishness, and the more negative, the greater the reddishness [2].

The higher the value of W or W_{10} , the higher the whiteness of the sample. However, the CIE standard includes the following restriction:

The application of the formulae is restricted to samples that are called 'white' commercially, that do not differ much in color and fluorescence, and that are measured on the same instrument at nearly the same time; within these restrictions, the formulae provide relative, but not absolute, evaluations of whiteness that are adequate for commercial use, when employing measuring instruments having suitable modern and commercially available facilities. The following

boundaries are proposed for the application of whiteness formulae:

$$40 < W \text{ or } W_{10} < 5Y - 280; \quad -3 < T_w \text{ or } T_{w,10} < +3, \quad (5)$$

where Y is the tristimulus value of the sample.

Development of the CIE Whiteness Formula

Whiteness is a commercially important property of color appearance in a number of industries, most notably those of textiles and paper. According to Wyszecki and Stiles, white is the attribute of a visual sensation according to which a given stimulus appears to be void of any hue and grayness [3]. Alternatively, the percept of whiteness is caused by a combination of high lightness and lack of yellowness [4]. MacAdam published the first instrumental method for the assessment of whiteness in 1934 [5], and by the 1960s, over 100 different methods to predict perceptual whiteness had been proposed. Although color is a three-dimensional percept, whiteness has traditionally been measured using a univariant metric. Hayhurst and Smith suggest that the reason for this is that the color of white textile or paper is often influenced by the quantity of a specific (single) impurity in it [4]; the white color therefore falls on a line in three-dimensional color space, albeit one that is curved. However, especially when different products are being compared, it is important to have a metric that is at least dependent upon all three dimensions of color space even if the metric is condensed to a single number, as is the case with the CIE whiteness method. Many of the early whiteness formulae considered only one or two of the three dimensions of color and therefore had limited general applicability.

The foundations for a modern and effective whiteness formula began with Ganz [6] who proposed a new generic formula for whiteness W_G in 1972 with the following form:

$$W_G = DY + Px + Qy + C, \quad (6)$$

where Y and x , y are the Y tristimulus value (sometimes called luminous reflectance) and chromaticity coordinates, respectively, of the sample, and D , P , Q , and C are coefficients that could be varied to adjust for various parameters including the illuminant, the observer, and the hue preference. The coefficient of D was set to unity and $C = P_{x,n} + Q_{y,n}$. Ganz suggested three pairs of values for P and Q each corresponding to a different hue preference. The formula was linear in chromaticity space because experience in producing white scales had shown that the chromaticities of uniformly spaced samples turn out to be approximately equidistant in this space [7].

A round-robin test [7], organized by a technical committee (TC-1.3) of the CIE in the 1970s, showed that there are individuals with extreme hue preference for whiteness. This suggests that a single whiteness formula cannot reproduce the whiteness preferences of a sizable portion of the population and this is why Ganz originally suggested three pairs of values for P and Q . The CIE adopted a form of Eq. 6 with values of P and Q corresponding to neutral hue preference, and the CIE equation is normally written in the forms

of Eqs. 1 and 2. The use of unity for the coefficient D has the implication that the whiteness of a perfect reflecting diffuser would be 100. Samples containing fluorescent whitening agents may have W or $W_{10} \gg 100$. The difference that is just perceptible to an experienced visual assessor is about three CIE whiteness units [4].

Ganz and Griesser developed a generic formula for the instrumental evaluation of tint [8]. Lines of equal tint run approximately parallel to the line of dominant wavelength 470 nm (467.6 and 464.7 nm, respectively, for the 1931 and 1964 CIE standard observers) in the chromaticity diagram. Figure 1 shows the line of dominant wavelength 470 nm and also two lines of iso-whiteness according to the CIE whiteness equation. The CIE adopted the Ganz-Griesser tint formula as part of the CIE whiteness standard.

The whiteness formula should be used only for the comparison of samples that are commercially white and do not differ much in color or fluorescence. The samples should be measured on the same instrument at the same time. The light source in the spectrophotometer used to measure the reflectance factors should match, as closely as possible, the illuminant D65. The requirement for instruments that could deliver consistent light

CIE Whiteness,

Fig. 1 CIE 1964 chromaticity diagram showing the line at dominant wavelength of 465 nm and two lines of iso-whiteness. The *upper* iso-whiteness line shows the locus of points with $W_{10} = 100$, passing through the white point; each point on this line has the same whiteness but a different tint. The *lower* iso-whiteness line shows the locus of points with $W_{10} = 120$. Whiteness generally increases from the *yellowish* part of the diagram to the *bluish* part

output (including in the near UV) that closely matches illuminant D65 led to developments in instrument-calibration techniques toward the end of the twentieth century.

Further Considerations and Future Directions

Since the introduction of the CIE whiteness equation, the approximately uniform color space, CIELAB, has been developed. This led some practitioners to want to calculate CIE whiteness in CIELAB space directly. Ganz and Pauli [9] developed the following equations that approximate the CIE whiteness and tint equations in the CIE (1976) $L^*a^*b^*$ space for the 1964 standard observer:

$$W_{10} = 2.41L^* - 4.45b^*[1 - 0.0090(L^* - 96)] - 141.4, \quad (7)$$

and

$$T_{w,10} = -1.58a^* - 0.38b^*, \quad (8)$$

where L^* , a^* , and b^* are the CIELAB coordinates of the sample. The upper limit $W_{10} < 5Y - 280$ was transformed by a linear approximation yielding $W_{10} < 10.6L^* - 852$. The other limits $W_{10} > 40$ and $-3 < T_{w,10} < 3$ remained unchanged.

The CIE whiteness formula has been found to correlate with visual assessments for many white samples where the tint is similar and where the level of fluorescence is comparable [10]. However, the level of agreement is much less when there are different tints and levels of fluorescence [10]. Observers frequently give the highest whiteness estimation to fluorescent-whitened samples with a hint of red, blue, or green. This is called “preferred white.” Uchida considered data from 26 observers who evaluated the whiteness of 49 fluorescent-whitened samples and devised a new whiteness formula W_u where

$$W_u = W_{10} - 2(T_{w,10})^2 \quad (9)$$

The Uchida equation [10] was recommended for samples where $40 < W_{10} < 5Y - 275$ and was found to give better agreement with the visual results than the CIE equation. In a recent study [11], 22 observers were asked to rank 20 samples (with low to high CIE whiteness indices). Results showed a significant consistency between the variations in the ordering decisions of the observers for the white samples with low CIE whiteness index but a high level of disagreement between the observers for the whiter samples.

Recently the generic form of the CIE whiteness equation (Eq. 2) with modified coefficients has been shown to be able to predict the whiteness of human teeth even though many of the samples would not be considered to be commercially white in the textile, plastic, and paper industries in which the CIE whiteness equation has traditionally been applied [12].

CIE 1994 (ΔL^* ΔC^*_{ab} ΔH^*_{ab}); ΔE^*_{94} ; Hue Difference, Delta H

Definition

The CIE94 color-difference formula [1] was developed by the CIE Technical Committee 1–29 “Industrial Color Difference Evaluation” chaired by Dr. D.H. Alman (USA). CIE94 is a CIELAB-based color-difference formula where CIELAB lightness, chroma, and hue differences are appropriately weighted by very simple “weighting functions” correcting CIELAB’s lack of visual uniformity, as well as by “parametric factors” accounting for the influence of illuminating/viewing conditions in color-difference evaluation. CIE94 may be considered a simplified version of the CMC color-difference formula [2], as well as a predecessor of currently CIE-recommended color-difference formula, the joint ISO/CIE standard CIEDE2000 [3, 4].

Overview

In 1976, CIE recommended the CIELUV and CIELAB color spaces with their corresponding color-difference formulas, defined as Euclidean distances in such spaces. These two color spaces

are only approximately uniform, and it was indicated that the use of different weighting for lightness, chroma, and hue differences may be necessary in different practical applications [5]. CIELAB has been widely accepted in many industrial applications [6], and in the past recent years, several CIELAB-based color-difference equations have been proposed to improve its performance. Among these formulas, we can mention, in chronological order, JPC79 [7], CMC [2], BFD [8], and CIE94. Nowadays, it is generally agreed that most of these formulas significantly improved CIELAB [9].

Assuming that subindices 1 and 2 indicate the two samples in a color pair, the next equations define the CIE94 color-difference formula, designated as $\Delta E^*_{94}(k_L:k_C:k_H)$:

$$\Delta E^*_{94}(k_L : k_C : k_H) = \sqrt{\left(\frac{\Delta L^*}{k_L S_L}\right)^2 + \left(\frac{\Delta C^*_{ab}}{k_C S_C}\right)^2 + \left(\frac{\Delta H^*_{ab}}{k_H S_H}\right)^2} \quad (1)$$

where the CIELAB lightness, chroma, and hue differences are given by

$$\Delta L^* = L^*_1 - L^*_2 \quad (2)$$

$$\Delta C^*_{ab} = C^*_{ab,1} - C^*_{ab,2} \quad (3)$$

$$\Delta H^*_{ab} = 2\sqrt{C^*_{ab,1}C^*_{ab,2}} \sin\left(\frac{\Delta h_{ab}}{2}\right) \quad (4)$$

$$\Delta h_{ab} = h_{ab,1} - h_{ab,2}. \quad (5)$$

The “weighting functions” for lightness (S_L), chroma (S_C), and hue (S_H) are defined as

$$S_L = 1 \quad (6)$$

$$S_C = 1 + 0.045\left(C^*_{ab,1}C^*_{ab,2}\right)^{1/2} \quad (7)$$

$$S_H = 1 + 0.015\left(C^*_{ab,1}C^*_{ab,2}\right)^{1/2}, \quad (8)$$

and the “parametric factors” k_L , k_C , k_H are set as 1.0 (i.e., do not affect the total color difference computation) under the next illuminating/viewing

conditions, usually known as “reference conditions”:

- Illumination: D65 source
- Illuminance: 1000 lx
- Observer: Normal color vision
- Background field: Uniform, neutral gray with $L^* = 50$
- Viewing mode: Object
- Sample size: Greater than 4 degrees
- Sample separation: Direct edge contact
- Sample color-difference magnitude: Lower than 5.0 CIELAB units
- Sample structure: Homogeneous (without texture)

In the textile industry, it is common practice to set the lightness parametric factor k_L to 2. Although the experimental conditions leading to this parametric correction to lightness difference are not yet well understood, it introduces important improvements in the performance of CIE94, which in this case must be designated as ΔE^*_{94} (2:1:1) or CIE94 (2:1:1).

For a constant ΔE^*_{94} value, Eq. 1 approximately represents [10] an ellipsoid with semiaxis lengths given by the denominators $k_L S_L$, $k_C S_C$, $k_H S_H$. Under reference conditions, the semiaxis lengths S_L , S_C , S_H are often denominated lightness, chroma, and hue tolerances, respectively. Equation 6 indicates that lightness tolerance is the same for all color centers. However, Eq. 7

indicates that chroma tolerances increase with chroma; that is, human sensitivities to chroma differences are smaller for color centers with higher chroma, as earlier pointed out by McDonald [11]. Similarly, Eq. 8 also indicates that hue tolerances/sensitivities increase/decrease with chroma. In summary, assuming small color differences [10], the loci of constant CIE94 differences in CIELAB color space can be represented by ellipsoids with constant lightness semiaxes, which sections in the a^* , b^* plane are ellipses with their major axes pointing to the origin (i.e., ellipses radially oriented). The major and minor semiaxes of these a^* , b^* ellipses linearly increase with the chroma of the ellipse centers (Fig. 1).

Development

The development of CIE94 [12, 13] began with a selection of experimental visual datasets meeting the next main conditions: statistical significance (i.e., to represent a population average with its corresponding uncertainty), well-documented experimental conditions, and use of object color specimens. CIE TC 1–29 decided to use only three experimental datasets: Witt [14, 15], Luo and

CIE94, History, Use, and Performance,

Fig. 1 CIE94 color-tolerance ellipses (or contours of approximately constant CIE94 units) in the a^* , b^* plane. (Figure from R. S. Berns [13], p. 121, graph courtesy of S. Quan)

Rigg [16], and RIT-DuPont [17, 18]. The main goal was to use these datasets to find the best weighting functions S_L , S_C , S_H correcting CIELAB. The analyses also considered the characteristics of the previous CMC color-difference formula, which was an ISO standard in textiles [19] and was successfully employed in different industries.

As indicated by Eqs. 7 and 8, it was found that simple linear chroma functions described the main trends in the experimental datasets analyzed. Both the lightness dependence of lightness tolerances and the hue angle dependence of hue tolerances proposed by the CMC color-difference formula were found not robust trends in the experimental datasets analyzed [13], and therefore they were disregarded in CIE94. It is possible that these two corrections proposed by CMC were influenced by some specific parametric factors. Anyway, it can be said that CIE94 was a conservative approach incorporating only the main corrections to CIELAB. Currently, the CIEDE2000 color-difference formula has incorporated additional corrections to CIELAB. For example, CIEDE2000 proposes a V-shaped function for the S_L function, which is different to both the lightness function proposed by CMC and the simple $S_L = 1$ adopted by CIE94.

CIE94 was the first CIE-recommended color-difference formula incorporating the influence of illuminating/viewing experimental conditions in color-difference evaluations through the use of the so-called parametric factors k_L , k_C , k_H (see Eq. 1).

The work carried out by CIE TC 1–29 finished with the proposal of CIE94 and some guidelines for coordinated future work on industrial color-difference evaluation [20]. These guidelines updated those earlier given by Robertson [21], proposing a new set of 17 color centers to be studied in future research, considering the effects of changes from the “reference conditions,” and suggesting the development of a database of color-difference visual responses.

Performance

From the combined dataset employed at CIEDE2000 development [22], the performance

of different color-difference formulas has been tested using the *STRESS* index [23]. Low *STRESS* values (always in the range 0–100) indicate better color-difference formula performance. *STRESS* values for CIELAB, CIE94, and CIEDE2000 are 43.9, 32.1, and 27.5, respectively [24]. As we can see, the improvement achieved by CIE94 upon CIELAB was considerably higher than the one achieved by CIEDE2000 with respect to CIE94. From *STRESS* values, it can be also concluded that in CIE94 the S_C function (which was also adopted in CIEDE2000) is a much more important correction to CIELAB than the S_H function [24]. Besides CIE94 being proposed for object colors, it has been reported that this formula also performed satisfactorily for self-luminous color datasets [25].

Curiously, Eqs. 7 and 8 involve the geometrical mean of the CIELAB chroma of the two samples in the color pair, in place of the more simple arithmetical mean proposed in other color-difference formulas, for example, CIEDE2000. Strictly speaking, this implies that the locus of constant CIE94 differences with respect to a given color center is not an ellipsoid/ellipse, although deviations from ellipsoidal/elliptical contours can be considered negligible in most practical situations. CIE94 color differences computed using the geometrical and arithmetical means of the CIELAB chroma of the samples in the color pair are slightly different, in particular for colors with very low chroma [26].

In comparison with other recent formulas like JPC79, CMC, BFD, or CIEDE2000, it can be said that CIE94 was relevant because it was a very simple and versatile color-difference formula accounting for the main robust trends found in reliable color-difference visual datasets. CIE94 just proposes to use simple corrections to CIELAB provided by the weighting functions S_L , S_C , S_H plus consideration of the influence of the illuminating/viewing conditions using the parametric factors k_L , k_C , k_H . After the CIE94 proposal, CIE TC 1–47 continued further work leading to the last CIE-recommended color-difference formula, CIEDE2000, which significantly improved CIE94 for the experimental datasets used in its development [22].

[CIE color appearance model 2002](#)

Definition

CIECAM02 is a color appearance model that provides a viewing condition specific method for transforming between tristimulus values and perceptual attribute correlates. This model was first published [1] in 2002 by Division 8 of the International Commission on Illumination (CIE). CIECAM02 was developed for use in color management systems and was based on the previously published CIECAM97s color appearance model [2, 3]. The model provides a number of parameters for defining a viewing condition and also inverse equations for transforming perceptual attribute correlates back to tristimulus values for a given set of viewing conditions. In this way, CIECAM02 can be used to transform perceptual attribute correlates, such as lightness, chroma, and hue, across different viewing conditions.

Overview

A color appearance model [4, 5] transforms between colorimetry, which specifies if stimuli match, and perceptual attribute correlates, which are scales of lightness, chroma, and hue. To do so,

CIECAM02 provides a set of viewing condition parameters in order to model specific color appearance phenomena, such as chromatic adaptation and simultaneous contrast. The resulting perceptual attribute correlates can then be used in research and engineering applications requiring a viewing condition independent color representation, such as color calibration of color printers.

The viewing conditions for CIECAM02 consist of the background, the adapting field, the surround, the white point, and the luminance of the adapting field. Figure 1 shows an example of a color stimulus, a background, and an adapting field. Note that this example is of a real-world situation of viewing a reflectance print. The central stimulus is a 2° region that corresponds to a portion of the print the size of a thumb viewed at arm's length. The background is the 10° region surrounding the stimulus and is roughly the size of a fist viewed at arm's length. The adapting field is everything else in the field of view.

The luminance of the adapting field can be measured directly with an illuminance meter. To incorporate a gray-world assumption and convert to luminance, this is then divided by 5π . The surround setting for the model is categorical and follows roughly the specific application. Dark

CIECAM02, Fig. 1 An example of a colored stimulus, background, and adapting field. The stimulus subtends 2° or roughly the size of a thumb viewed at arm's length. The background subtends 10° or approximately the size of a fist viewed at arm's length. The adapting field is everything

else in the field of view. The stimulus is shown as the *central smaller black circle*. The background is shown as the *larger black circle*. The adapting field is everything outside of the *larger black circle*

surrounds are those with no ambient illumination or viewing film projected in a darkened room. Dim surrounds are those in which the ambient illumination is not zero but is also less than 20% of the scene, print, or display white point, such as home viewing of television with low light levels. Average surround is ambient illumination greater than 20% of the scene, print, or display white point, such as viewing of surface colors in a light booth. The CIECAM02 model has a set of constants associated with each surround.

Finally the model has an associated white for all calculations. The selection of a white point is a subtle topic and the model suggests two approaches to this issue. First is to use an adopted white point or a computational white point for all calculations. An adopted white point is a fixed value, such as one based on a standard viewing condition or to ensure a specific final mapping for the white point. Second is an adapted white or the white point adapted by the human visual system for a given set of viewing conditions. An adapted white point is one which attempts to as closely as possible match the state of adaptation for a human observer. Note that adapted white points may require experimentation to infer their value, such as for a novel set of viewing conditions or situations with multiple illuminants. In cases where it is not possible to determine the adapted white

point, use of an adopted or assumed white point can be convenient.

Given a set of viewing conditions and their associated parameters, it is then possible to compute the perceptual attribute correlates. Figure 2 shows an overall flowchart of the CIECAM02 model starting with input tristimulus values and adopted white point tristimulus values on the left.

The first step is to apply a matrix to convert the XYZ values to the CAT02 RGB space. The space was selected as a preferred color space to perform chromatic adaptation. This matrix can be written:

$$M_{CAT02} = \begin{bmatrix} 0.7328 & 0.4296 & -0.1624 \\ -0.7036 & 1.6975 & 0.0061 \\ 0.0030 & 0.0136 & 0.9834 \end{bmatrix} \quad (1)$$

The result of applying this matrix to 1931 color matching functions is shown in Fig. 3. These curves can be compared to the CIE color matching functions, and it can be seen that these curves are qualitatively more narrow or sharpened. This matrix was derived using a set of corresponding color training data but excluding highly chromatic light sources.

The degree of adaptation is the next step in the model and is calculated given the surround setting

CIECAM02, Fig. 2 Overall flowchart of the computational steps for calculating perceptual attribute correlates given input tristimulus values and a specific set of viewing conditions

CIECAM02, Fig. 3 The CAT02 matrix shown as a set of *red*, *green*, and *blue* sensitivity curves computed by applying Eq. 1 to the CIE 1931 color matching functions

and the luminance of the adapting field. The specific calculation for incomplete adaptation or D is shown in Eq. 2. The variable L_A is the luminance of the adapting field and the value of F is a parameter that is computed from the surround setting.

$$D = F \left[1 - \left(\frac{1}{3.6} \right) e^{\left(\frac{-L_A - 42}{92} \right)} \right] \quad (2)$$

The results of using Eq. 2 with three different surround settings over luminance of adapting field values ranging from 0 to 800 cd/m^2 are shown in Fig. 4. Essentially the surround limits the degree of adaptation and increases with larger values of L_A . Complete adaptation is only achieved with the average surround with high L_A values.

Given the input stimulus converted to CAT02 RGB space and a degree of adaptation, it is then possible to compute the chromatic adaptation. This can be done according to Eqs. 3, 4, and 5 below. The stimulus CAT02 values are shown as R , G , and B and the adopted or adapted white point as R_w , G_w , and B_w .

$$R_c = [D(100/R_w) + 1 - D]R \quad (3)$$

$$G_c = [D(100/G_w) + 1 - D]G \quad (4)$$

$$B_c = [D(100/B_w) + 1 - D]B \quad (5)$$

The next step in the calculation of the forward CIECAM02 model is shown as the box HPE RGB

in the center of the flowchart in Fig. 2. This is the conversion of R_c , G_c , and B_c above to the Hunt-Pointer-Estevéz space. This can be done using a 3 by 3 matrix shown in Eq. 6:

$$\mathbf{M}_{HPE} = \begin{bmatrix} 0.38971 & 0.68898 & -0.07868 \\ -0.22981 & 1.18340 & 0.04641 \\ 0.00000 & 0.00000 & 1.00000 \end{bmatrix} \quad (6)$$

A plot of the corresponding red, green, and blue sensitivity curves for the Hunt-Pointer-Estevéz RGB space is shown in Fig. 5. This graph shows the red and green curves with qualitatively broader and more overlapping than the red and green curves for the CAT02 RGB curves shown in Fig. 3. Effort was made during the formulation of the model to derive a single RGB space for both the chromatic adaptation and for the nonlinear compression, but the results were generally worse and ultimately the final model made use of the two different RGB spaces.

Given the Hunt-Pointer-Estevéz RGB values, the next step is the nonlinear response compression. The specific nonlinearity used [6] in CIECAM02 is shown in Eqs. 7 through 9 and is shown graphically in Fig. 6. The R' , G' , and B' values are the HPE values as computed with Eq. 6, and the F_L value is a model parameter that is dependent on the viewing conditions.

CIECAM02, Fig. 4 The degree of adaptation as computed for three surrounds and varying L_A . A D value of 1 is complete adaptation to the white point, while values less than one are for incomplete adaptation

CIECAM02, Fig. 5 The HPE matrix shown as a set of *red*, *green*, and *blue* sensitivity curves computed by applying Eq. 6 to the CIE 1931 color matching functions

$$R'_a = \frac{400(F_L R' / 100)^{0.42}}{[27.13 + (F_L R' / 100)^{0.42}]} + 0.1 \quad (7)$$

$$G'_a = \frac{400(F_L G' / 100)^{0.42}}{[27.13 + (F_L G' / 100)^{0.42}]} + 0.1 \quad (8)$$

$$B'_a = \frac{400(F_L B' / 100)^{0.42}}{[27.13 + (F_L B' / 100)^{0.42}]} + 0.1 \quad (9)$$

The final steps in the forward CIECAM02 model are the computation of the perceptual attribute correlates. First an intermediate set of opponent coordinates, a and b , are computed according to Eqs. 10 and 11. It should be emphasized that these values of a and b are preliminary and should not be used directly. The value of h or hue is computed using the arctangent of b divided by a . A table of constants is used to compute H or hue quadrature. The resulting H values for red, yellow, green, and blue are 100, 200, 300, and 400, respectively.

CIECAM02, Fig. 6 The post-adaptation nonlinear response compression function as computed using Eq. 7. Similar curves result for Eqs. 8 and 9 for the calculation of G'_a and B'_a

$$a = R'_a - 12G'_a/11 + B'_a/11 \quad (10)$$

$$b = (1/9)(R'_a + G'_a - 2B'_a) \quad (11)$$

The perceptual attribute correlates for lightness and brightness can then be calculated. First the achromatic signal or A is computed according to Eq. 12. The R'_a , G'_a , and B'_a values are the non-linearly compressed values from Eqs. 7 through 9. Next the computation of J or lightness is shown in Eq. 13, while the computation of Q or brightness is shown in Eq. 14. The c and z values are additional model parameters as computed based on the viewing conditions.

$$A = [2R'_a + G'_a + (1/20)B'_a - 0.305]N_{bb} \quad (12)$$

$$J = 100(A/A_w)^{cz} \quad (13)$$

$$Q = (4/c)\sqrt{J/100}(A_w + 4)F_L^{0.25} \quad (14)$$

Finally given the correlates for hue, lightness, and brightness, it is possible to calculate the perceptual attribute correlates for chroma, colorfulness, and saturation. First a temporary variable t is computed using Eq. 15. Next C or chroma is calculated using Eq. 16. Colorfulness or M and saturation s can then be computed using Eqs. 17 and 18.

$$t = \frac{(50,000/13)N_c N_{cb} e_t (a^2 + b^2)^{1/2}}{R'_a + G'_a + (21/20)B'_a} \quad (15)$$

$$C = t^{0.9} \sqrt{J/100} (1.64 - 0.29^n)^{0.73} \quad (16)$$

$$M = CF_L^{0.25} \quad (17)$$

$$S = 100\sqrt{M/Q} \quad (18)$$

The result of the preceding calculations is then a set of perceptual attribute correlates for the given input values and viewing conditions. Note though that this does not define a rectangular coordinate system, such as the a^* and b^* values for CIELAB [7]. Instead a set of correlates such as lightness, chroma, and hue must first be computed and used as polar coordinates. The rectangular coordinates can be computed using Eqs. 19 and 20. Similar coordinates can be calculated for lightness and saturation, with subscript s , and brightness and colorfulness, with subscript M .

$$a_c = C \cdot \cos(h) \quad (19)$$

$$b_c = C \cdot \sin(h) \quad (20)$$

The inverse CIECAM02 equations are beyond the scope of this entry, but reference 1 contains the full steps for inverting the above equations. This

allows tristimulus values to be computed given input perceptual attribute correlates and viewing conditions.

The CIECAM02 color appearance model can then be used in situations requiring a viewing condition independent color encoding. It also could be considered in cases where CIELAB or CIELUV [7] lacks perceptual uniformity. For example, the CIELAB blue hue lacks hue constancy and tends toward purple as it approaches the neutral axis. This can be problematic in many circumstances, such as when gamut mapping colors from a display to a printer. The CIECAM02 space is considerably more uniform in this case. Two example gradients are shown in Fig. 7. The CIELAB gradient shown on the top has a clear tendency to purple as it goes to gray while the CIECAM02 gradient on the bottom does not. Both color spaces have constant hue angles for these colors but CIECAM02 is significantly improved.

It is useful to further compare and contrast CIELAB and CIECAM02. CIELAB has as input the stimulus XYZ values and the white point XYZ values. CIECAM02 has as input the stimulus and white XYZ values and also luminance of the adapting field, the luminance of the background, and the surround setting. CIELAB has a chromatic adaptation transform that consists of a complete von Kries transform in XYZ space, while CIECAM02 has a complete or incomplete von Kries transform in CAT02 RGB space. CIELAB has a cube-root nonlinearity, while CIECAM02 uses a modified hyperbolic function as the nonlinearity. CIELAB uses XYZ data to compute the opponent signal, while CIECAM02 is based on a

Hunt-Pointer-Estevéz space. Finally CIELAB can be used to compute lightness, chroma, and hue correlates, while CIECAM02 can be used to compute these values as well as brightness, colorfulness, saturation, and hue quadrature values. However, CIELAB has benefited from the additional research in advanced color difference equations and as a result has advanced color difference metrics such as ΔE_{94} and ΔE_{2000} which CIECAM02 does not have. There are encouraging results [8] though for using CIECAM02-based color difference equations.

Future Directions

CIECAM02 has been a useful and valuable addition to color appearance modeling research. It has provided a single reference point for ongoing research in the area of color appearance modeling. However, a number of researchers have pointed to specific aspects of the complexity that are problematic in some cases. For example, for the darkest colors, it may not be possible to invert the calculations for highly saturated inputs. These values may be outside the spectral locus, but for color management applications that use a fixed intermediate grid of coordinates, this is a shortcoming. Therefore, it seems likely that future work will continue in the area of color appearance modeling, with a future focus on robustness [8] and perhaps simplicity. In spite of these limitations, there is already work integrating CIECAM02 with color management systems, such as the International Color Consortium (ICC) [10, 11]. There has also been work [12] to

CIECAM02, Fig. 7 *Light gray to deep blue constant hue angle gradients for CIELAB, shown at the top, and CIECAM02 shown at the bottom. The left- and right-hand*

side colors are the same XYZ values and have constant respective hue angles, but the top gradient for CIELAB tends to a purplish tone in the center of the gradient

consider how the model could be further extended to encompass a wider range of viewing conditions, such as mesopic illumination levels. Finally, there is also research [13] in the area of how the model could be used with complex stimuli to create an image appearance model.

Definition

CIEDE2000 [1, 2] is a color-difference formula recommended by the CIE in year 2001. It has also recently been published as an ISO and CIE Joint Standard [3]. It is a modification of CIELAB [4] and gives an overall best performance in predicting experimental datasets. The typical applications are pass/fail decision, color constancy, metamerism, and color rendering.

Overview

Over the years, color scientists and engineers have been striving to achieve a single number pass/fail color-difference equation, i.e., to apply a single pass/fail color difference to all color regions for industrial quality control. In practice, product batches should be visually acceptable against a standard, when a color difference is less than a predetermined color-difference unit (called color tolerance). Reversely, it will be rejected to be returned for re-shading.

In 1976, CIELAB uniform color space was recommended by the CIE. The decision was

made based on limited experimental data. It was realized a shortage of reliable experimental data having similar color-difference magnitude as those used in industry (typically with CIELAB color difference (ΔE^*_{ab}) ≤ 5). Hence, many datasets were produced, in which four datasets were considered to be most comprehensive and robust and were used to derive the new formulae. These datasets are Luo and Rigg [5], RIT-DuPont [6], Witt [7], and Leeds [8]. They have 2776, 156, 418, and 307 pairs of samples and average

color differences of 3.0, 1.0, 1.9, and 1.6 ΔE^*_{ab} , respectively. All datasets were based on glossy paint samples except that of Luo and Rigg data, which include many subsets based on different materials, and finally all subsets were combined according to the experimental results based on textile samples [5].

Using these data, a series of equations were developed by modifying CIELAB. They all have a generic form as given in Eq. 1:

$$\Delta E = \sqrt{\left(\frac{\Delta L^*}{k_L S_L}\right)^2 + \left(\frac{\Delta C_{ab}^*}{k_C S_C}\right)^2 + \left(\frac{\Delta H_{ab}^*}{k_H S_H}\right)^2 + R_T \left(\frac{\Delta C_{ab}^*}{k_C S_C} \frac{\Delta H_{ab}^*}{k_H S_H}\right)} \quad (1)$$

where

$$\begin{aligned} \Delta L^* &= L_{ab,2}^* - L_{ab,1}^* \\ \Delta C_{ab}^* &= C_{ab,2}^* - C_{ab,1}^* \\ \Delta H_{ab}^* &= 2\sqrt{C_{ab,2}^* C_{ab,1}^*} \sin\left(\frac{\Delta h_{ab}}{2}\right) \\ \text{where } \Delta h_{ab} &= h_{ab,2} - h_{ab,1} \end{aligned}$$

and subscripts 1 and 2 are the two samples in a pair. The R_T is an interactive term between ΔC_{ab}^* and ΔH_{ab}^* . The S_L , S_C , and S_H are weighting factors for the correlates of L^* , C_{ab}^* , and h_{ab} and are dependent on the positions of the samples in a pair. The k_L , k_C , and k_H are parametric factors to take into account the surface characteristics of the materials in question such as textile, paint, and plastic. Equation 1 is a form of ellipsoid along the directions of CIELAB lightness, chroma, and hue angle. The ellipsoid can also be rotated in C_{ab}^* and h_{ab} plane. Four equations were developed after CIELAB in 1976. These were Leeds [8], BFD [9], CIE94 [10] and CMC [11]. The CMC was adopted by the ISO for textile applications in 1992 [11]. The CIE94 was recommended by the CIE for field trials in 1994. Both equations have the first three terms of Eq. 1, and BFD and Leeds include all four terms. All formulae greatly outperform CIELAB to fit the experimental datasets. Industry was confused which equation

should be used. Hence, CIE Technical Committee (TC) 1–47 *Hue and Lightness-Dependent Correction to Industrial Colour Difference Evaluation* was formed in 1998. It was hoped that a generalized and reliable formula could be achieved.

The TC members worked closely together and a formula named CIEDE2000 was recommended [1, 2]. The computation procedure of this formula is given in Eq. 2.

CIEDE2000 ($K_L:K_C:K_H$) Color-Difference Formula

The input of the equation is two sets of CIELAB values for the samples of the pair in question. The procedure to calculate CIEDE2000 is given below:

Step 1. Prepare data to calculate a' , C' , and h' .

$$L' = L^*$$

$$a' = (1 + G)a^*$$

$$b' = b^*$$

$$C'_{ab} = \sqrt{a'^2 + b'^2}$$

$$h_{ab} = \tan^{-1} \left(\frac{b'}{a'} \right)$$

where

$$G = 0.5 \left(1 - \sqrt{\frac{\overline{C_{ab}^*}^7}{\overline{C_{ab}^*}^7 + 25^7}} \right)$$

where $\overline{C_{ab}^*}$ is the arithmetic mean of the C_{ab}^* values for a pair of samples.

Step 2. Calculate $\Delta L'$, $\Delta C'$, and $\Delta H'$.

$$\Delta L' = L'_2 - L'_1$$

$$\Delta C'_{ab} = C'_{ab,2} - C'_{ab,1}$$

$$\Delta H'_{ab} = 2 \sqrt{C'_{ab,2} C'_{ab,1}} \sin \left(\frac{\Delta h'_{ab}}{2} \right)$$

$$\text{where } \Delta h'_{ab} = h'_{ab,2} - h'_{ab,1}$$

Step 3. Calculate CIEDE2000 ΔE_{00} .

$$\Delta E_{00} = \sqrt{\left(\frac{\Delta L'}{k_L S_L} \right)^2 + \left(\frac{\Delta C'_{ab}}{k_C S_C} \right)^2 + \left(\frac{\Delta H'_{ab}}{k_H S_H} \right)^2 + R_T \left(\frac{\Delta C'_{ab}}{k_C S_C} \right) \left(\frac{\Delta H'_{ab}}{k_H S_H} \right)}$$

where

$$S_L = 1 + \frac{0.015 (\overline{L'} - 50)^2}{\sqrt{20 + (\overline{L'} - 50)^2}}$$

and

$$S_C = 1 + 0.045 \overline{C'_{ab}}$$

and

$$S_H = 1 + 0.015 \overline{C'_{ab}} T$$

where

$$T = 1 - 0.17 \cos(\overline{h'_{ab}} - 30^\circ) + 0.24 \cos(2\overline{h'_{ab}}) + 0.32 \cos(3\overline{h'_{ab}} + 6^\circ) - 0.20 \cos(4\overline{h'_{ab}} - 63^\circ)$$

and

$$R_T = -\sin(2\Delta\theta) R_C$$

where

$$\Delta\theta = 30 \exp \left\{ - \left[\left(\overline{h'_{ab}} - 275^\circ \right) / 25 \right]^2 \right\}$$

$$\text{and } R_C = 2 \sqrt{\frac{\overline{C'_{ab}}^7}{\overline{C'_{ab}}^7 + 25^7}}$$

(2)

Note that $\overline{L'}$, $\overline{C'_{ab}}$, and $\overline{h'_{ab}}$ are the arithmetic means of the L' , C'_{ab} , and h'_{ab} values for a pair of samples. For calculating the $\overline{h'_{ab}}$ value, caution needs to be taken for neutral colors having hue angles in different quadrants, e.g., Sample 1 and

Sample 2 with hue angles of 90° and 300° would have a mean value of 195° , which differs from the correct answer, 15° . This can be obtained by checking the absolute difference between two hue angles. If the difference is less than 180° , the arithmetic mean should be used. Otherwise, 360°

should be subtracted from the larger angle, followed by calculating of the arithmetic mean. This gives $300-360^\circ = -60^\circ$ for the sample and a mean of $(90-60^\circ)/2 = 15^\circ$ in this example.

Three-Term CIEDE2000 Color-Difference Formula

The CIEDE2000 color-difference equation described above includes four terms. In many applications, a three-term equation is required such as for shade sorting and color tolerance specification, indicating direction to a specific difference in recipe prediction. Hence, a three-term CIEDE2000 version was also developed [12] and is Eq. 3:

$$\Delta E_{00} = \left[(\Delta L_{00})^2 + (\Delta C_{00})^2 + (\Delta H_{00})^2 \right]^{1/2} \quad (3)$$

where

$$\Delta L_{00} = \frac{\Delta L'}{k_L S_L}; \quad \Delta C_{00} = \frac{\Delta C''}{S_C''}; \quad \Delta H_{00} = \frac{\Delta H''}{S_H''}$$

and

$$\begin{aligned} \Delta C'' &= \Delta C' \cos(\varphi) + \Delta H' \sin(\varphi) \\ \Delta H'' &= \Delta H' \cos(\varphi) - \Delta C' \sin(\varphi) \end{aligned}$$

$$\text{where } \tan(2\varphi) = R_T \frac{(k_C S_C) (k_H S_H)}{(k_H S_H)^2 - (k_C S_C)^2}$$

where φ is taken to be between -90° and 90° . If $k_H S_H = k_C S_C$, then 2φ is equal to 90° and φ is equal to 45° :

$$\begin{aligned} S_C'' &= (k_C S_C) \sqrt{\frac{2(k_H S_H)}{2(k_H S_H) + R_T(k_C S_C) \tan(\varphi)}} \\ S_H'' &= (k_H S_H) \sqrt{\frac{2(k_C S_C)}{2(k_C S_C) - R_T(k_H S_H) \tan(\varphi)}} \end{aligned}$$

where $\Delta L'$, $\Delta C'$, and $\Delta H'$ and S_L , S_C , S_H , k_L , k_C , and k_H are the same as those in Eq. 2.

The ΔE_{00} value calculated from Eq. 3 is the same as calculated from Eq. 2.

Evaluation of the CIEDE2000

The typical way to evaluate each formula's performance is to apply statistical measures. One measure, standardized residual sum of squares (STRESS) index [13], has been widely used as given in Eq. 4. It measures the discrepancy between the calculated color difference (ΔE) and visual difference (ΔV) from an experimental dataset:

$$\text{STRESS} = 100 \sqrt{\frac{\sum (\Delta E_i - f \Delta V_i)^2}{f^2 \sum \Delta V_i^2}} \quad (4)$$

$$\text{where } f = \frac{\sum \Delta E_i^2}{\sum \Delta E_i \Delta V_i}$$

STRESS values are ranged between 0 and 100. For a perfect agreement, STRESS value should be zero. It can be considered as a percentage error prediction. Table 1 gives the performance of the four equations tested using the previous mentioned four datasets together with COM dataset which was combined with a weight for each of the four datasets.

It can be seen in Table 1 that CIEDE2000 gave an overall best performance. In addition, CIELAB performed the worst. CIEDE2000 performed significantly better than the other formulae except insignificantly better than CIE94 for the Leeds and RIT-DuPont sets.

Another widely used method to evaluate color-difference equations is to use color discrimination ellipses. Figure 1 shows that the experimental ellipses (in black color) obtained from the Luo and Rigg dataset plotted against those (in red color) predicted by CIEDE2000. The color discrimination ellipse is an effective way to represent a number of color-difference pairs in a color center. The color differences between points in the ellipse and the color center represent equal visual color difference. If CIELAB formula agrees perfectly with the experimental results, all ellipses should be constant radius circles. Hence, the pattern shown in Fig. 1 indicates a poor performance of CIELAB, i.e., very small ellipses close to neutral axis; ellipse sizes increase when chroma increases.

CIEDE2000, History, Use, and Performance,

Fig. 1 Experimental color discrimination ellipses plotted in a^*b^* diagram. (Copyright of the Society of Dyers and Colourists)

Comparing the experimental and CIEDE2000 ellipses, both sets fit well, especially in the blue region. (Note that the experimental ellipses for all other color regions generally point toward the neutral except that the blue ellipses point away from the neutral axis. This effect implies that both CMC and CIE94 formulae do fit well to the experimental results in the region.)

Future Directions

This section showed an outstanding color-difference equation, CIEDE2000, which has been recommended by the CIE. It fits the datasets having magnitude of industrial color differences well. However, it does not have an associated color space. A summary of the future direction on color difference is given below.

- Almost all of the recent efforts have been spent on the modifications of CIELAB. This has resulted in CIEDE2000 including five corrections of CIELAB to fit the available experimental datasets. It is desirable to derive a formula based upon a new perceptually uniform color space from a particular color vision theory such as CIECAM02 [14].
- All color-difference formulae can only be used in a set of reference viewing conditions defined by the CIE [10]. It will be valuable to derive a parametric color-difference formula capable of taking into account different viewing parameters such as illuminant, illuminance level, size of samples, size of color difference, separation, and background. Again, CIECAM02 model and its extension CAM02-UCS [15] are derived to follow this direction.
- Almost all of the color-difference formulae were developed only to predict the color

difference between a pair of large single objects/patches. More and more applications require to predict color differences between a pair of pictorial images. The current formula does not include necessary components to consider spatial variations for evaluating images. Johnson and Fairchild developed a spatial model based on CIEDE2000 [16].

Definition

CIELAB is a uniform color space (UCS) recommended by CIE in 1976 [1], and it was later published as a Joint ISO/CIE Standard [2]. A UCS is defined by the CIE International Lighting Vocabulary [3] as a color space in which equal distances are intended to represent threshold or suprathreshold perceived color differences of equal size. It is one of the most widely used color spaces. The typical applications include color specification and color difference evaluation. The former is to describe a color in perceptual correlates such as lightness, chroma, and hue and to plot samples to understand their relationships. The latter is mainly used for color quality control such as setting color tolerance, color constancy, metamerism, and color rendering.

For the definition equations of the components of CIELAB, see section CIE L*a*b* Formula (CIELAB).

Overview

Over the years, color scientists and engineers have been striving to achieve a UCS. To apply UCS, a pair of samples will first be measured by a color measuring instrument to obtain their CIE tristimulus values (XYZ) which will then be transformed to the perceptual correlates such as CIELAB lightness, chroma, and hue angle. The distance between a pair of colors is calculated and reported as color difference (ΔE). This difference will then be judged against a predetermined color tolerance which could be a particular color region and a product. For a particular product, all pairs should be judged as “acceptable,” when the color difference is less than the color tolerance. Otherwise, it will be rejected. A good color difference formula is also called a “single number pass/fail formula,” i.e., to apply a single color tolerance to all color regions.

Over 20 formulae were derived before the recommendation of CIELAB in 1976 [4]. Some of them were derived to fit the spacing of the Munsell color order system. The concept of the Munsell color order system was invented by A. H. Munsell and was based on steps of equal visual perception. Any color can be defined as a point in

a three-dimensional Munsell color space. Its associated attributes are Munsell hue (H), Munsell chroma (C), and Munsell value (V) which correspond to the perceived hue, saturation, and lightness, respectively. The spacing of the color samples for each attribute was intensively studied by the members in the Colorimetry Committee of the Optical Society of America (OSA), and the CIE tristimulus values of ideally spaced samples were published in 1943 [5].

Figure 1 shows the loci for samples having constant Munsell chroma and curves for samples having constant Munsell hue. Since the Munsell samples are based on equal visual steps, for a perfect agreement between the Munsell data and a color space, all loci should be circles with a constant increment between all neighboring chroma steps. As shown in Fig. 1, this is obviously not the case, i.e., one step of chroma in the blue region is at least five times shorter than one step of chroma in the green region. Additionally, all iso-chroma loci are far from being circles, and no iso-hue contours are straight lines. These indicate that there is a very large difference between the Munsell system and the CIE system represented by x, y chromaticity diagram.

Some earlier Munsell-based formulae are directly calculated using Munsell H, V, and C values with a weighting factor for each component. In 1944, ANLAB was developed by Adams and Nickerson [6] as given in Eq. 1.

$$\Delta E_{\text{ANLAB}} = \sqrt{40 \left\{ (0.23 \Delta V_y)^2 + [\Delta(V_x - V_y)]^2 - 0.4 [\Delta(V_y - V_z)]^2 \right\}} \quad (1)$$

and

$$I = 1.2219 V_1 - 0.23111 V_1^2 + 0.23591 V_1^3 \\ - 0.021009 V_1^4 + 0.00084045 V_1^5$$

where I corresponds to X , Y , or Z tristimulus values. In Eq. 1, the terms of $(V_x - V_y)$ and $0.4(V_y - V_z)$ correspond to the ANLAB

a (redness-greenness) and b (yellowness-blueness) scales, respectively. By adding the third scale $0.23V_y$, ANLAB becomes a three-dimensional UCS. It was recommended by the Colour Measurement Committee (CMC) of the Society of Dyers and Colourists (SDC) and became an ISO standard in 1971 for the application in the textile industry. A series of cube root formulae were also derived to simplify the

CIELAB, Fig. 1 Constant Munsell chroma loci and constant Munsell hue curves at Munsell values of 5 plotted in the CIE chromaticity diagram. (From Billmeyer and Saltzman [14])

ANLAB formula which involves a cumbersome fifth-order polynomial function. This resulted in CIELAB color difference formula introduced in 1976 [1]. CIELAB units include L^* , a^* , and b^* ; the asterisk is used to differentiate the CIELAB system from ANLAB.

In 1976, the CIE recommended two uniform color spaces, CIELAB (or CIE $L^*a^*b^*$) and CIELUV (or CIE $L^*u^*v^*$), as it was still not possible to decide which one would correspond better to visual observations.

CIE $L^*a^*b^*$ Formula (CIELAB)

CIELAB equation is given in Eq. 2.

$$\begin{aligned} L^* &= 116f(Y/Y_n) - 16 \\ a^* &= 500[f(X/X_n) - f(Y/Y_n)] \\ b^* &= 200[f(Y/Y_n) - f(Z/Z_n)] \end{aligned} \quad (2)$$

where

$$f(I) = I^{1/3}, \text{ for } I > \left(\frac{6}{29}\right)^3$$

Otherwise,

$$F(I) = \frac{841}{108}I + \frac{16}{116}$$

X, Y, Z and X_n, Y_n, Z_n are the tristimulus values of the sample and a specific reference white considered. It is common to use the tristimulus values of a CIE standard illuminant as the X_n, Y_n, Z_n values. Correlates of L^* , a^* , and b^* are lightness, redness-greenness, and yellowness and blueness, respectively.

Correlates of hue and chroma are also defined by converting the rectangular a^*, b^* axes into polar coordinates (see Eq. 3). The lightness (L^*), chroma (C_{ab}^*), and hue (h_{ab}) correlates

correspond to perceived color attributes, which are generally much easier to understand for describing colors.

$$\begin{aligned} h_{ab} &= \tan^{-1}(b^*/a^*) \\ C^*_{ab} &= \sqrt{a^{*2} + b^{*2}} \end{aligned} \quad (3)$$

Color difference can be calculated using Eq. 4.

$$\Delta E^*_{ab} = \sqrt{\Delta L^{*2} + \Delta a^{*2} + \Delta b^{*2}} \quad (4)$$

or

$$\Delta E^*_{ab} = \sqrt{\Delta L^{*2} + \Delta C^{*2}_{ab} + \Delta H^{*2}_{ab}}$$

where

$$\Delta H^*_{ab} = 2 \left(C^*_{ab,1} C^*_{ab,2} \right)^{1/2} \sin \left[\frac{(h_{ab,2} - h_{ab,1})}{2} \right] \quad (5)$$

and subscripts 1 and 2 represent the samples of the pair considered; the ΔL^* , Δa^* , Δb^* , ΔC^*_{ab} , and ΔH^*_{ab} are the difference of L^* , a^* , b^* , C^*_{ab} , and hue in radiant unit (see Eq. 5) between Samples 1 and 2, respectively.

Figure 2 shows the CIELAB color space. It can be seen that the rectangular coordinates consist of L^* , a^* , and b^* . A positive and negative values of a^* represent reddish and greenish colors, respectively. A positive and negative values of b^* represent yellowish and bluish colors, respectively. For the polar coordinates, hue angle is ranged from 0° to 360° following a rainbow scale from red, yellow, green, blue, and back to red. The 0° , 90° , 180° , and 270° approximate pure red, yellow, green, and blue colors (or unitary hues). Chroma starts from zero origin of neutral axis having chroma of zero and then increases its chromatic content to become more colorful. The colors located in the cylinder of Fig. 4 have a constant chroma, equally perceived chroma content around the hue circle.

CIELAB, Fig. 2 Illustration of CIELAB color space

Evaluation of CIELAB Color Space

Two sets of data are used here to evaluate the performance of CIELAB space. Figure 3 shows the constant Munsell chroma loci and constant Munsell hue curves at Munsell values of 5 plotted in CIELAB a^*b^* diagram. It can be seen that the pattern is close to the expectation of a good UCS, i.e., the constant chroma loci are close to circle and constant hue radius are close to a straight line (hue constancy). The uniformity of CIELAB is much better than that of CIE chromaticity diagram (see Fig. 1). However, detailed inspection can be found that the same chroma value in yellow and blue regions could still differ by a factor of almost 2. Also, the constant hue line is very much curved in the areas of orange, blue, and green yellow.

After the recommendation of the CIELAB formula, some experimental datasets having $\Delta E^*_{ab} \leq 5$ (representing typical magnitude of industrial color differences) were produced. These sets in general agree with each other. They were later selected to be used to derive different

CIELAB, Fig. 3 Constant Munsell chroma loci and constant Munsell hue curves at Munsell values of 5 plotted in the CIELAB a^*b^* diagram

color difference formulae. Figure 4 shows the experimental ellipses obtained from the Luo and Rigg dataset [7]. The dataset includes more color centers and covers a much larger color gamut than the others. A color discrimination ellipse represents the points on the circumference of the ellipse against the center of the ellipse to have the same visual difference. If CIELAB formula agrees perfectly with the experimental results, all ellipses should be constant radius circles. The figure shows the poor performance of CIELAB. For example, all ellipses close to neutral are much smaller than those in the saturated color regions.

The results given in Figs. 3 and 4 clearly showed the effect of performance that different experimental results could disagree with each other greatly. The discrepancy between the Luo and Rigg and Munsell datasets is mainly due to the color difference magnitude used in the experimental datasets. CIELAB performs not badly for the large color differences with ΔE^*_{ab} about 10 units (see Fig. 3), but predicts very poorly for smaller color differences ($\Delta E^*_{ab} \leq 5$) (see Fig. 4).

Future Directions

Since the recommendation of CIELAB in 1976, many equations were derived by modifying CIELAB such as CMC [8], CIE94 [9], and the more recent CIE recommendation CIEDE2000 [10]. They do fit the datasets ($\Delta E^*_{ab} \leq 5$) well. However, they do not have an associated color space. The future directions on color difference are given below.

- It is desirable to derive a formula based upon a new perceptually uniform color space from a model of color vision theory such as CIECAM02 [11]. A uniform color space is based upon this color appearance model, like CAM02-UCS [12].
- All color difference formulae can only be used in a set of reference viewing conditions defined by the CIE [10]. It will be valuable to derive a parametric color difference formula capable of taking into account different viewing parameters such as illuminant, illuminance level, size

CIELAB, Fig. 4 Luo and Rigg experimental color discrimination ellipses plotted in $a^* b^*$ diagram

of samples, size of color difference, separation, and background. Again, the CIECAM02 model [11] and its extension, CAM02-UCS [12], are equipped with these capabilities.

- Almost all of the color difference formulae were developed only to predict the color difference between a pair of individual patches. More and more applications require evaluating color differences between a pair of pictorial images. Johnson and Fairchild developed a formula for this purpose [13].

Definition

Using the L^* , a^* , and b^* coordinates of the CIELAB uniform color space as the three component values of a 24-bit digital image.

CIELAB

Overview

CIE 1976 (L^* , a^* , b^*) color space (or CIELAB) is widely used for image encoding and processing applications as diverse as color management, gamut mapping, color interchange, and color quality evaluation. What makes CIELAB

attractive for these applications is its being an approximately uniform color space. A perceptually uniform scale generally enables the most efficient use of bits and the least visible artifacts when images are digitized for viewing by human observers.

CIELAB Color Space

In CIELAB color space a color stimulus is expressed in terms of L^* , a^* , and b^* rectangular coordinates. The entry on CIELAB gives the formulas for calculating L^* , a^* , b^* values from the X , Y , Z tristimulus values of the color stimulus and the X_n , Y_n , Z_n tristimulus values of the reference white object color stimulus. CIELAB color space can be traced to the Munsell system, which was based on evaluating suprathreshold color differences of isolated reflective patches viewed against a gray background.

In the CIELAB color space, the L^* value represents the lightness value of the stimulus. A stimulus that reflects no radiation over the visible wavelength band has an L^* value of zero, while the perfectly diffusing reflector under the illuminant with tristimulus values X_n , Y_n , Z_n has an L^* value of 100. Stimuli with tristimulus values that are proportional to those of the reference white color stimulus will have a^* and b^* values of zero. This means that CIELAB is an opponent color space: a gray or achromatic stimulus with the same chromaticities as the normalizing white stimulus will lie on the L^* axis, with black at one end and white at the other. The cube root formula for L^* is a close approximation of the relationship between the Munsell value V and luminance factor Y/Y_n , so L^* is essentially the Munsell value scaled up by a factor of 10. The distance of a stimulus from the L^* axis is given by the chroma value C^*_{ab} .

In an ideal perceptually uniform color space, the Euclidean distance between two color stimuli would correspond to the perceived difference between them. Ideally, then, pairs of color stimuli would look equally different if the three-dimensional distance between them in CIELAB color space, i.e., ΔE^*_{ab} , was the same, independent of the difference being along the L^* , a^* , or b^* dimension or some combination of them. A ΔE^*_{ab}

of 1 is generally considered a just perceptible difference, although the threshold depends on how the stimuli are compared and what part of color space they lie in because CIELAB is only approximately uniform. Since 1976, the CIE has published two extensions to the CIE 1976 $L^*a^*b^*$ color-difference formulas to improve perceptual uniformity in the calculation of color differences, i.e., CIE94 and CIEDE2000.

Figure 1 plots the a^* and b^* axes for CIE standard illuminants D_{50} and D_{65} on the x-y chromaticity diagram. In very rough terms, the a^* axis runs from cyan to magenta and the b^* axis, from blue to yellow. The range of a^* and b^* values is determined by the collection of samples at hand or that a given device can generate. Fig. 2 shows selected L^* planes of the volume generated in CIELAB color space by the MacAdam limits for reflectance materials with respect to CIE standard illuminants D_{50} and D_{65} . For the L^* planes shown in Fig. 2, the a^* values range from -163 to 126.6 for illuminant D_{50} and from -168.2 to 145.6 for illuminant D_{65} ; the b^* values range from -129.6 to 145.1 for illuminant D_{50} and from -127.7 to 145.3 for illuminant D_{65} . These are theoretical limits on the values that can be obtained with reflectance materials.

The ranges obtained with object color stimuli encountered in practice with printed and

photographic materials will be much less than the MacAdam limits. For example, Fig. 3 shows the Pointer colors measured with illuminant C, which has a correlated color temperature close to that of CIE illuminant D_{65} . An update to the Pointer gamut with a revised set of stimuli and for CIE illuminant D_{50} is under development as this is being written.

Quantization and Dynamic Range

A desirable property of a color space for image encoding is that it covers as large a gamut as needed with the fewest number of levels or digital values. Too many levels are wasteful; too few and an image will show visible contours or bands due to the lower precision in the quantization. Banding is most noticeable in areas with smooth gradients. If the sampling of values or quantization in color space is not fine enough, small differences in the original color values of adjacent pixels in such areas will become larger and potentially visible color differences after quantization. The usual solution is to ensure the quantization is fine enough, especially in the regions of color space where the human visual system is most sensitive to color differences. The addition of noise also can help. If the quantization is mathematically uniform, then quantizing the color space everywhere the same means that the quantization

CIELAB for Color Image Encoding (CIELAB, 8-Bit; Domain and Range, Uses), Fig. 1 a^* , b^* axes on a CIE x-y chromaticity diagram with (a) CIE standard illuminant D_{50} and (b) CIE standard illuminant D_{65} as normalizing illuminant

D_{65} . (Figure is based on data generously provided by Prof. Francisco Martinez-Verdú of the Colour & Vision Group at the University of Alicante)

CIELAB for Color Image Encoding (CIELAB, 8-Bit; Domain and Range, Uses), Fig. 3 a^* and b^* values of the Pointer colors for L^* planes from 15 to 90

will be finer than it needs to be in regions of color space less sensitive to color differences, which is inefficient.

The optimum solution for a uniform color quantization of rendered images is to use a perceptually uniform color space. (*Rendered images* are defined here to mean images intended to be directly viewed by human observers.) This

solution would use the fewest levels for a given limit on the maximum color error in the quantization or sampling process. This performance is achieved with a three-dimensional quantization based on a body-centered cubic lattice [1, 2], which would also give the minimum mean squared error if the input color stimuli were uniformly distributed [3]. A one-dimensional

quantization based on a simple cubic lattice and that samples each CIELAB coordinate L^* , a^* , and b^* independently would be suboptimal but more straightforward to implement. Another reason for less than optimal performance is that CIELAB is only approximately uniform. The divergence of CIELAB from true perceptual uniformity has led to extensions to improve upon various nonuniformities. Nevertheless, the original CIELAB color space is still widely used for many color imaging applications.

For one-dimensional quantization, 8 bits are sufficient to quantize the range of a^* or b^* values for reflection images typically encountered in practice. While 7 bits would be enough to represent numerical values from 0 to 100, the use of 8 bits generally would be more convenient in a digital system. Moreover, there are perceptual grounds for using a minimum of 8 bits to quantize the L^* coordinate in color images. As mentioned earlier, isolated color patches were used in the development of the Munsell system to which CIELAB color space can be traced. When such patches abut along a sharp edge, smaller color differences are detectable. There are historical data [4] and more recent analysis [5] to justify scaling the L^* value up to 8 bits so that the just noticeable differences along the L^* , a^* , and b^* axes across a sharp edge are more nearly equal. Also, the greater weighting given to L^* differences in color-difference equations in some applications recognizes a generally greater sensitivity to luminance differences compared to chromatic differences.

While there may be room for discussion and debate about the exact value of the scaling factor to use for the lightness coordinate, from the beginning standard engineering practice has been to use 8 bits when encoding L^* in color images [2, 6]. Some CIELAB applications, especially those in which CIELAB-encoded images may later be subjected to significant amounts of additional image processing, may instead specify 12 or 16 bits per coordinate.

CIELAB image data is generated by converting linear tristimulus or image values. Since CIELAB is a nonlinear transform of

(linear) XYZ tristimulus values, 12 bits of tristimulus values are needed to address all 256 levels in an 8-bit CIELAB system in order to minimize quantization errors and banding. Nonlinear 8-bit-per-coordinate RGB encodings such as sRGB can be converted to CIELAB using a combination of matrices and one-dimensional lookup tables as long as sufficiently greater bit precision is used in the intermediate conversion stages. Three-dimensional lookup tables are often used for such conversions.

Because CIELAB was developed to be a mathematical representation of the Munsell system – an approximately uniform space based on reflective color patches – it follows that CIELAB should be well suited for encoding images on reflection media having luminance dynamic ranges and chromaticity boundaries similar to those of the Munsell system color set. In practice, this often is the case. Color images on most reflection media can be encoded satisfactorily in terms of 24-bit (8 bits per channel) CIELAB values if those values are used judiciously. In particular, the luminance dynamic range of the image medium generally should not exceed a visual density range of about 2.50 (a luminance ratio of just over 300:1). The exact luminance dynamic range that can be encoded in terms of 8-bit CIELAB L^* values will depend on a number of factors, most notably the amount of noise in the images. The greater the noise, the less visible quantization artifacts such as contouring will be. In many imaging systems, the noise inherent in the original images and the additional noise contributed by scanners, display devices, and media are sufficient to mask quantization artifacts. However, in other cases, such as virtually noise-free digitally created images, noise in the form of dithering may need to be computationally added in order to avoid unacceptable quantization when 8-bit-per-channel CIELAB encoding is used.

Encoding in terms of 8-bit-per-channel CIELAB values sometimes can be problematic even when applied to images on reflection media or other imaging media or devices having comparable luminance dynamic ranges. In particular, undesirable banding and other artifacts may result

if the encoded images are subjected to significant additional image processing. For example, if an image encoded at 8-bit-per-channel CIELAB is appreciably lightened or darkened by subsequent signal processing, quantization effects that originally may have been subthreshold may become visible in image shadow or highlight areas of the processed image. In an extreme case, image processing might be used to reverse the sign of an image, e.g., to make a positive original image into a negative image. In that case, the L^* quantization of the original image would no longer be appropriate for the transformed image, and undesirable quantization effects likely would result.

Another consideration for 8-bit-per-channel CIELAB encoding, as well as for virtually any other 8-bit-per-channel encoding, is its applicability for rendered images having luminance dynamic ranges or chromaticity gamuts significantly greater than those of the Munsell system. For example, imaging devices such as digital projectors and media such as photographic slide films and motion picture films have luminance dynamic ranges considerably greater than those of typical reflection media. When the perceived lightness of such images is first appropriately adjusted for observer general brightness adaptation and then expressed in terms of CIELAB values, the resulting L^* values can range from well below 1.0 to well over 100 [7]. The luminance dynamic ranges of high dynamic range (HDR) digital projectors and other HDR display devices are even greater, and the primaries of such devices can be capable of producing chromaticity color gamuts much larger than that of the Munsell system. In addition, images to be encoded may be colorimetric representations of original scenes rather than of rendered reproductions. Unrendered scene colorimetric values may be in the form of camera RAW values from a digital camera, computationally derived values from scans of color negatives or other photographic media, or values produced by computer-generated imaging (CGI). Such values can greatly exceed those that can be adequately represented by virtually any 24-bit encoding metric, including 8-bit-per-channel color encodings based on CIELAB and other color spaces derived from the Munsell system.

CIELAB Encodings

Different image formats and the applications that use them have made different encoding choices for CIELAB. One of the first standards to define a CIELAB encoding for image and document processing applications was the Xerox Color Encoding Standard [8]. Since then the TIFF, PDF, and JPX formats also have defined CIELAB encodings.

An obvious way to digitally encode L^* , a^* , and b^* values is to convert them to integer values. The TIFF CIELAB encoding [9] does this, using an unsigned integer value for L^* and signed integer values for a^* and b^* . Other encodings have been designed that use unsigned integers and map the L^* , a^* , and b^* values encountered in practice to match the 8-bit range so as to reduce quantization errors by making best use of the 8 bits available for encoding the values.

When CIELAB is used for image encoding, then the two main choices are:

- What does the L^* range represent?
- What mapping should be used to encode the a^* and b^* values?

The following equations map L^* , a^* , and b^* values to 8-bit encoded L , A , and B values:

$$\begin{aligned} L &= \text{scale}_L \times L^* + \text{offset}_L \\ &= \frac{255}{(L_{\max}^* - L_{\min}^*)} (L^* - L_{\min}^*) \end{aligned}$$

$$\begin{aligned} A &= \text{scale}_A \times a^* + \text{offset}_A \\ &= \frac{255}{(a_{\max}^* - a_{\min}^*)} (a^* - a_{\min}^*) \end{aligned}$$

$$\begin{aligned} B &= \text{scale}_B \times b^* + \text{offset}_B \\ &= \frac{255}{(b_{\max}^* - b_{\min}^*)} (b^* - b_{\min}^*) \end{aligned}$$

The encodings can be described using either scale and offset parameters or the minimum and maximum values that are mapped to the 8-bit values 0 and 255. In some formats, the encoding parameters are defined by the format; in others,

the user can explicitly set them with default values usually available.

In most formats the L scale factor $scale_L$ is 255/100 and the L offset parameter $offset_L$ is 0. The equivalent minimum and maximum L^* values are 0 and 100. This means that L^* values of 0 and 100 are encoded as 0 and 255. This is the default L^* encoding in TIFF and PDF. In these formats, an L^* value of 100 corresponds to the perfect diffusing reflector under the specified illuminant. In the case of the TIFF CIELAB encoding, the illuminant is not part of the encoding specification. PDF requires that the diffuse white point be specified. Specifying the illuminant is optional in JPX, which uses CIE illuminant D_{50} as the default. A question sometimes asked is what illuminant should be used with CIELAB. The answer is the reference illuminant used to measure or calibrate the XYZ or RGB values from which the CIELAB values were derived.

The a^* and b^* values typically encountered in practice lie within the 8-bit range from -128 to 127 so they can be encoded using a scale factor of

1 and an offset of 0, which is what the TIFF CIELAB encoding does [9]. The encoded A and B values that result are signed 8-bit integers. The TIFF ICCLAB encoding [10] uses an offset value of 128 instead so that the encoded A and B values are unsigned 8-bit integers, as they are in the 8-bit encoding that the International Color Consortium (ICC) profile format standard uses when CIELAB is the profile connection space [11]. Figure 4 shows the encoded L , A , and B components for the TIFF ICCLAB encoding of a sample image, where a^* and b^* values of 0 are encoded as 128.

Since the ranges of typical a^* and b^* values are usually much less than 255, a scale factor greater than 1 (or equivalently a maximum-minimum difference of less than 255) would expand the range encountered in practice to fill the full range available with 8 bits. The TIFF ITULAB encoding [12] allows an application to specify the minimum and maximum values of a^* and b^* that map to the encoded values 0 and 255. This encoding matches the CIELAB encoding used by color facsimile [13]. PDF [14] provides the same CIELAB encoding for images. JPX [15], the extended

CIELAB for Color Image Encoding (CIELAB, 8-Bit; Domain and Range, Uses), Fig. 4 Clockwise from *upper left*, original color image and its L^* , a^* , and b^* components encoded using the TIFF ICCLAB encoding

version of the JP2 base file format for JPEG 2000, provides an equivalent capability by allowing an application to specify the ranges of a^* and b^* values that map onto the range of 8-bit values and the offsets to go with them.

Besides using the full range available with an 8-bit encoding, scaling the a^* and b^* values also reduces quantization errors, especially when image compression is used. This was important for color facsimile, where reasonable transmission times require the use of moderate to high levels of JPEG compression, which can lead to visible “blockiness” in the decompressed image. Scaling the a^* and b^* values reduces the effects of the quantization error caused by aggressive JPEG compression. The default scaling defined in the ITU color facsimile standards was based on the range obtained by measuring a wide range of hardcopy materials; the range was -85 to $+85$ for a^* and -75 to $+125$ for b^* . The default illuminant for the CIELAB encoding is CIE illuminant D_{50} . The color facsimile standards allow color fax machines to negotiate the use of custom a^* and b^* ranges and other illuminants.

The case for scaling up the L^* values encountered in practice to fill the full 8-bit range is less compelling since the values encountered in practice already cover most of the available range. For example, the minimum and maximum reflectance values for the reference medium defined by the ICC are 0.30911% and 89%, corresponding to a visual density range of about 2.46 (a luminance ratio of about 288:1) and minimum and maximum L^* values of 2.79 and 95.58, using the perfectly diffusing reflector as the white reference. While higher dynamic ranges with L^* values greater than 100 originating from scenes and photographic

films can be modified to fit within an 8-bit range, the results can be loss of detail due to the tone compression and limited precision provided by 8 bits in those cases.

Table 1 compares 8-bit CIELAB encodings in terms of the defaults for minimum and maximum L^* , a^* , and b^* values and whether the format allows an application to set the ranges for L^* , a^* , or b^* . While the focus here is on 8-bit encodings, these formats also support 16-bit CIELAB encodings.

In the CIELAB encodings described thus far, an L^* value of 100 corresponds to the perfectly diffusing reflector under the specified illuminant. This is not always the case with the CIELAB encoding that the ICC defines for the profile connection space (PCS). The PCS is the color space to or from which input and output device coordinates can be transformed. (Besides CIELAB, the PCS may also use an XYZ encoding.) This makes it possible to connect an arbitrary input device to an arbitrary output device via the PCS in an ICC-based color management system, since a device only needs to know how to transform its coordinates to or from PCS coordinates. Such transforms are defined in device profiles. Transforms can have different intents such as perceptual, where the objective is a pleasing reproduction, or colorimetric, where the objective is a colorimetrically accurate reproduction of the tristimulus values.

Lookup table-based profiles for the *perceptual* rendering intent on input, output, and display devices all use CIELAB as the PCS; both 8- and 16-bit versions are defined. The CIELAB values of the PCS are calculated with XYZ tristimulus values that are normalized with respect to the media white point under CIE illuminant D_{50} rather

CIELAB for Color Image Encoding (CIELAB, 8-Bit; Domain and Range, Uses), Table 1 Default component ranges for 8-bit CIELAB encodings

Format – encoding	L^*		a^*		b^*		Range settable
	Min	Max	Min	Max	Min	Max	
TIFF – CIELAB	0	100	-128	127	-128	127	No
TIFF – ICCLAB	0	100	-128	127	-128	127	No
TIFF – ITULAB	0	100	-85	85	-75	125	L^*, a^*, b^*
PDF – Lab	0	100	-100	100	-100	100	a^*, b^*
JPX – CIELab	0	100	-85	85	-75	125	L^*, a^*, b^*

CIELAB for Color Image Encoding (CIELAB, 8-Bit; Domain and Range, Uses), Fig. 5 a^* and b^* values of the ISO 12640-3 reference color gamut for L^* planes from 5 to 95

than the perfectly diffusing reflector. (The PCS CIELAB values for the *colorimetric* intent are calculated with reference to the perfectly diffusing reflector.) In keeping with the orientation to graphic arts and desktop publishing applications, V4 of the ICC specification [11] defined the reference medium for calculating the PCS values of the perceptual rendering as a reflection print on a substrate with a neutral reflectance of 89% and where the darkest printable color has a neutral reflectance of 0.30911%. Therefore, the L^* value of the unprinted substrate is 100 and of the darkest printable color is 3.1373. With the 8-bit CIELAB encoding used for the PCS, these values are scaled and encoded as 255 and 8, respectively. A scale factor of 1 and an offset of 128 are used for the a^* and b^* values, as in the TIFF ICCLAB encoding.

The adoption of a reference medium, and subsequently of a reference medium gamut, was designed to improve interoperability within an ICC-based workflow using the perceptual intent. Because a perceptual transform from source to destination media usually required gamut mapping, the gamut of the reference medium used for the PCS was explicitly defined. Besides specifying the endpoints of the L^* scale of the perceptual reference medium, this meant specifying the a^* and b^* limits as well. For this the ICC used the

reference color gamut defined in ISO 12640-3 [16] and shown in Fig. 5. As with the PCS, the L^* , a^* , and b^* values in Fig. 5 were calculated using the reference medium (instead of the perfectly diffusing reflector) with CIE illuminant D_{50} as the reference white object color in the L^* , a^* , and b^* equations. The ISO 12640-3 standard also specifies a set of TIFF (specifically TIFF/IT) images with 16-bit CIELAB values that use the ICC PCS encoding and are within the limits of the reference gamut in Fig. 5.

Conclusions

Based on this discussion, it can be concluded that 8-bit-per-channel CIELAB is appropriate and well suited for digitally encoding color images when all of the conditions below apply:

- The images to be encoded are rendered reproductions.
- The luminance dynamic range and overall color gamut of the images are consistent with those of the Munsell system.
- Appropriate mathematical transformations, such as scale factors and offsets, are used to

maximize the efficiency of the CIELAB encoding.

- Relatively limited subsequent image processing is applied to CIELAB-encoded images.

Clapper-Yule Model

Mathieu Hébert

ERIS Group, CNRS, UMR 5516, Laboratoire Hubert Curien, Université de Lyon, Université Jean Monnet de Saint-Etienne, Saint-Etienne, France

Definition

The Clapper-Yule model is a physically based model describing the reflection of spectral light fluxes by a printed surface and enabling the prediction of halftone prints on diffusing substrates [1]. The model relies on a closed-form equation obtained by describing the multiple transfers of light between the substrate and the print-air interface through the inks. Physical parameters are attached to the inks, the diffusing support, and the surface. The model assumes that the lateral propagation distance of light within the substrate, due to scattering, is much larger than the halftone screen period. Most photons therefore cross different ink dots while traveling in the print. The

reflections and transmissions of light at the surface are explicitly taken into account depending on the print's refractive index, as well as the considered illumination and measuring geometries.

The Clapper-Yule Equation

The Clapper-Yule equation derives from the description of multiple reflections of light between the substrate and the print-air interface, represented in Fig. 1. The substrate, strongly diffusing, has a spectral reflectance $r_g(\lambda)$. The print-air interface reflects on its two sides: On the top side, a fraction r_s of the incident light is reflected toward the detector (this fraction may be zero according to the geometry of illumination and detection). A fraction T_{in} enters the print. On the back side, a fraction r_i is reflected and a fraction T_{ex} exits the print toward the detector. Regarding the inks, the model assumes that they are located between the surface and the substrate. If N different inks are used, the halftone is a mosaic of 2^N colors, also called *Neugebauer primaries*, resulting from the partial overlap of the ink dots. In the case of typical cyan, magenta, and yellow inks, there are eight Neugebauer primaries: white (no ink), cyan, magenta, yellow, red (magenta + yellow), green (cyan + yellow), blue (cyan + magenta), and black

(cyan + magenta + yellow). Each primary occupies a fractional area a_i on the surface and transmits a fraction $t_i(\lambda)$ of the light. The global attenuation for light crossing the halftone ink layer is therefore:

$$\sum a_i t_i(\lambda).$$

By denoting, $I_0(\lambda)$ and $I_1(\lambda)$ the downward fluxes illuminating the surface, respectively, the substrate, and as $J_0(\lambda)$ and $J_1(\lambda)$ the upward fluxes exiting the surface, respectively, the substrate, the following relations are obtained:

$$\begin{aligned} J_0(\lambda) &= r_s I_0(\lambda) + \left[T_{ex} \sum a_i t_i(\lambda) \right] J_1(\lambda), I_1(\lambda) \\ &= \left[T_{in} \sum a_i t_i(\lambda) \right] I_0(\lambda) + \left[r_i \sum a_i t_i^2(\lambda) \right] J_1(\lambda), J_1(\lambda) \\ &= r_g(\lambda) I_1(\lambda), \end{aligned}$$

from which is deduced the spectral reflectance $R(\lambda)$ of the halftone print:

$$R(\lambda) = \frac{J_0(\lambda)}{I_0(\lambda)} = r_s + \frac{T_{in} T_{ex} r_g(\lambda) [\sum a_i t_i(\lambda)]^2}{1 - r_i r_g(\lambda) \sum a_i t_i^2(\lambda)}.$$

This equation is the general Clapper-Yule equation. In their original paper, Clapper and Yule considered halftones of one ink, with surface coverage a and transmittance $t(\lambda)$:

Clapper-Yule Model,
Fig. 1 Transfers of light flux between the print-air interface and the diffusing substrate

$$R(\lambda) = r_s + \frac{T_{in}T_{ex}r_g(\lambda)[1 - a + at(\lambda)]^2}{1 - r_i r_g(\lambda)[1 - a + at^2(\lambda)]}.$$

If one Neugebauer primary covers the whole surface (“solid primary layer”), the equation becomes:

$$R(\lambda) = r_s + \frac{T_{in}T_{ex}r_g(\lambda)t^2(\lambda)}{1 - r_i r_g t^2(\lambda)},$$

and in the special case where no ink is printed (white colorant), it expresses the reflectance of the printing support:

$$R(\lambda) = r_s + \frac{T_{in}T_{ex}r_g(\lambda)}{1 - r_i r_g(\lambda)}.$$

Fresnel Terms and Measuring Geometries

The terms T_{in} , T_{ex} , r_s , and r_i are derived from the Fresnel formulae for unpolarized light. The Fresnel reflectivity of an interface between media 1 and 2, with respective indices n_1 and n_2 , is denoted as $R_{12}(\theta)$ when the light comes from medium 1 at the angle θ . The term T_{in} depends on the illumination geometry. It is typically:

$$T_{in} = 1 - R_{12}(\theta)$$

when directional light incomes at angle θ , or

$$T_{in} = 1 - \int_{\theta=0}^{\pi/2} R_{12}(\theta) \sin 2\theta \, d\theta$$

when the incident light is perfectly diffuse. T_{ex} depends on the measuring geometry. When the print is observed in one direction θ' , it is:

$$T_{ex} = (n_1/n_2)^2 T_{12}(\theta')$$

where the factor comes from the change of solid angle containing the exiting radiance due to the refraction. When an integrating sphere captures all light reflected by the print, it is:

$$T_{ex} = 1 - \int_{\theta=0}^{\pi/2} R_{21}(\theta) \sin 2\theta \, d\theta.$$

The term r_s corresponds to the surface reflection, i.e., the gloss. It depends on the illumination and observation geometries, by it is typically 0.05 when it is captured, or 0 when it is discarded from measurement.

The reflectance r_i is the fraction of diffuse light emerging from the substrate which is reflected by the surface. It corresponds to the Lambertian reflectance of flat interfaces:

$$r_i = \int_{\theta=0}^{\pi/2} R_{21}(\theta) \sin 2\theta \, d\theta.$$

For example, for a print made of material of refractive index 1.5 illuminated by directional light at 45° and observed at 0° (so-called $45^\circ/0^\circ$ measuring geometry), one has [2]:

$$\begin{aligned} T_{in} &= 1 - R_{12}(45^\circ) = 0.95, \\ T_{ex} &= T_{01}(0^\circ)/n^2 = \frac{1}{n^2} \left[1 - \frac{(1-n)^2}{(1+n)^2} \right] = 0.42, \\ r_s &= 0, \\ r_i &= 0.6. \end{aligned}$$

The Clapper-Yule equation becomes:

$$R(\lambda) = \frac{0.4r_g(\lambda)[\sum a_i t_i(\lambda)]^2}{1 - 0.6r_g(\lambda) \sum a_i t_i^2(\lambda)}.$$

Calibration of the Model and Prediction

The calibration of the model requires measuring the spectral reflectance of a few halftones, as the one represented in Fig. 2 in the case of CMY halftones.

By measuring the spectral reflectance $R_{w\text{left}}(\lambda)$ of the unprinted support (patch in row A of Fig. 2), whose expression is given above, one deduces the intrinsic spectral reflectance of the substrate thanks to the following formula:

Clapper-Yule Model, Fig. 2 Colors to be printed and measured using a spectrophotometer to calibrate the Clapper-Yule model in the case of CMY halftones

$$r_g(\lambda) = \frac{R_w(\lambda) - r_s}{T_{in}T_{ex} + r_i(R_w(\lambda) - r_s)}.$$

Then, by measuring the spectral reflectances $R_i(\lambda)$ of the solid primary patches (patches in row B of Fig. 2), whose expression is given above, one deduces the intrinsic spectral reflectance of the substrate thanks to the following formula:

$$t_i(\lambda) = \sqrt{\frac{R_i(\lambda) - r_s}{r_g(\lambda)[T_{in}T_{ex} + r_i(R_i(\lambda) - r_s)]}}.$$

All spectral parameters are now known. The spectral reflectance of a given halftone can be predicted by the Clapper-Yule general equation as soon as the surface coverages of different primaries are known. In classical clustered-dot or error diffusion prints, the primary surface coverages can be deduced from the surface coverages of the inks according to the Demichel equations. In the case of CMY halftones, the Demichel equations relating the surface coverages of the eight primaries to the surface coverages c , m , and y of the cyan, magenta, and yellow inks are:

$$\begin{aligned} a_w &= (1 - c) (1 - m) (1 - y), \\ a_c &= c(1 - m) (1 - y), \\ a_m &= (1 - c)m(1 - y), \\ a_y &= (1 - c) (1 - m)y, \\ a_{m+y} &= (1 - c)my, \\ a_{c+y} &= c(1 - m)y, \\ a_{c+m} &= cm(1 - y), \\ a_{c+m+y} &= cmy. \end{aligned}$$

Note that the prediction accuracy of the model sensibly depends on the exactitude of the primary surface coverage values. When the inks spread on the surface, which is almost always the case, the values for c , m , and y are larger than the ones defined in prepress. This phenomenon is generally called *dot gain*. The amount of ink spreading cannot be estimated by advance as it depends on several parameters, such as the chemical and mechanical properties of the inks and of printing support as well as the halftone pattern. They therefore need to be estimated from measurement.

Each ink i is printed alone on paper at the nominal surface coverages $q_i = 0.25, 0.5$, and 0.75 , which correspond to the nine color patches represented in rows C, D, and E of Fig. 2. Their

respective spectral reflectances are denoted as $R_{q_i}^{(m)}(\lambda)$. These halftones contain two primaries: the ink which should occupy a fractional area q_i and the paper white which should occupy the fractional area $1 - q_i$. Applying the Clapper-Yule equation with these two primaries and these surface coverages should predict a spectral reflectance $R_{q_i}^{(p)}(\lambda)$ equal to the measured one, but due to the fact that the effective ink surface coverage is different from the nominal one, these two reflectances are not the same. The effective surface coverage q_i' as the q_i value minimizing the deviation between predicted and measured spectra, by quantifying the deviation either by the sum of square differences of the components of the two spectra, i.e.,

$$q_i' = \arg \min_{0 \leq q_i \leq 1} \sum_{\lambda=\lambda_{\min}}^{\lambda_{\max}} \left[R_{q_i}^{(p)}(\lambda) - R_{q_i}^{(m)}(\lambda) \right]^2$$

or by the sum of square difference of the components of their logarithm, i.e.,

$$q_i' = \arg \min_{0 \leq q_i \leq 1} \sum_{\lambda=\lambda_{\min}}^{\lambda_{\max}} \left[\log R_{q_i}^{(p)}(\lambda) - \log R_{q_i}^{(m)}(\lambda) \right]^2$$

or by the corresponding color difference given, e.g., by the CIELAB metric

$$q_i' = \arg \min_{0 \leq q_i \leq 1} \Delta E_{94} \left(R_{q_i}^{(p)}(\lambda), R_{q_i}^{(m)}(\lambda) \right).$$

The first method is the most classical way of determining the effective surface coverage. Taking the log of the spectra as in the second method has the advantage of providing a higher weight to lower reflectance values where the visual system is more sensitive to small spectral differences. Fitting q_i' from the color difference metric sometimes improves the prediction accuracy of the model but complicates the optimization. Even at the optimal surface coverage q_i' , the difference between the two spectra is rarely zero and provides a first indication of the prediction accuracy achievable by the model for the corresponding print setup.

Once the nine effective surface coverages are computed, assuming that the effective surface coverage is 0, respectively 1, when the nominal surface coverage is 0 (no ink), respectively 1 (full coverage), three sets of q_i' values are obtained which, by linear interpolation, yield the continuous ink spreading functions f_i (Fig. 3). As an alternative, one can print halftones at nominal surface coverage 0.5 only and perform parabolic interpolation [3]. The number of patches needed for establishing the ink spreading curves is thus reduced to three (row C in Fig. 2).

Once the spectral parameters and the ink spreading functions are computed, the model is calibrated. The spectral reflectance of prints can be predicted for any nominal ink surface coverages c , m , and y . The ink spreading functions f_i

Clapper-Yule Model, Fig. 3 Example of ink spreading curves f obtained by linear interpolation of the effective surface coverages q_{ij}' deduced from the measured spectral

reflectances of patches with single-ink halftones (ink i) printed at nominal surface coverages 0.25, 0.5, and 0.75

directly provide the effective surface coverages c' , m' , and y' of the three inks:

$$\begin{aligned} c' &= f_c(c), \\ m' &= f_m(m), \\ y' &= f_y(y). \end{aligned}$$

Plugging these effective ink surface coverages into the Demichel equations, one obtains the eight effective primary surface coverages, and the general equation of the model finally predicts of the reflectance spectrum of the considered halftone.

Improved Ink Spreading Assessment Method

Hersch et al. observed that a given ink spreads differently according to whether it is printed alone on paper or superposed with another ink. They proposed an ink spreading assessment method taking into account the superposition conditions of the inks in the halftone [4]. This method increases noticeably the model's prediction accuracy. It relies on the halftones represented in Fig. 2 as well as the ones represented in Fig. 4.

The nominal ink surface coverages c , m , and y are converted into effective ink surface coverages c' , m' , and y' by accounting for the superposition-dependent ink spreading. In the case of CMY halftones, 12 in. spreading curves are obtained, similar to the ones represented in Fig. 5.

The effective surface coverage of each ink is obtained by a weighted average of the ink spreading curves, the weights being the surface coverages of the respective primaries on which the ink

halftone is superposed. For example, the weight of the ink spreading curve f_c (cyan halftone over the white primary) is proportional to the surface of the underlying white primary, i.e., $(1 - m)(1 - y)$. First, $c' = c$, $m' = m$, and $y' = y$ are taken as initial values on the right side of the following equations:

$$\begin{aligned} c &= (1 - m)(1 - y)f_c(c_0) + m(1 - y)f_{c/m}(c_0) \\ &\quad + (1 - m)yf_{c/y}(c_0) + myf_{c/m+y}(c_0), \\ m &= (1 - c)(1 - y)f_m(m_0) + c(1 - y)f_{c/m}(m_0) \\ &\quad + (1 - c)yf_{m/y}(m_0) + cyf_{m/c+y}(m_0), \\ y &= (1 - c)(1 - m)f_y(y_0) + c(1 - m)f_{y/c}(y_0) \\ &\quad + (1 - c)m f_{y/m}(y_0) + cmf_{y/c+m}(y_0). \end{aligned}$$

The obtained values of c' , m' , and y' are then inserted again into the right side of the equations, which yield new values of c' , m' , y' , and so on, until they stabilize. The final values of c' , m' and y' are plugged into the Demichel equations in order to obtain the effective surface coverages of the eight primaries. The spectral reflectance of the considered halftone is finally provided by the Clapper-Yule equation.

Experimental Testing

In order to assess the prediction accuracy of the model, predicted and measured spectra may be compared on sets of printed colors. As comparison metric, one generally uses the CIELAB ΔE_{94} , obtained by converting the predicted and measured spectra first into CIE-XYZ tristimulus values, calculated with a D65 illuminant and in respect to a 2° standard observer, and then into

Clapper-Yule Model, Fig. 4 Additional colors to be printed and measured using a spectrophotometer to assess the superposition-dependent ink spreading in the case of CMY halftones

Clapper-Yule Model, Fig. 5 Example of ink spreading curves f_{ij} for each ink i superposed with solid layers of the other inks in the case of CMY halftones

CIELAB color coordinates using as white reference the spectral reflectance of the unprinted paper illuminated with the D65 illuminant.

Because it assumes that the lateral propagation of light is large compared to the halftone screen period, the Clapper-Yule model is theoretically restricted to halftones with high screen frequency. For example, the model tested on two sets of 729 CMY colors printed with the same offset press on the same paper but at different frequencies, respectively, 76 and 152 lines per inch (lpi), provides better predictions for the highest frequency (average ΔE_{94} of 0.98 unit) than for the lowest one (average ΔE_{94} of 1.26 unit). Nevertheless, the experience shows that the model may also perform well for middle and low frequencies: For a set of 40 CMY colors printed in ink-jet at 90 lpi on supercalendered paper, the model

achieves a fairly good prediction accuracy, denoted by the average ΔE_{94} of 0.47 unit. Note that the average ΔE_{94} is 0.70 unit when the ink superposition conditions are not taken into account in the ink spreading assessment.

Conclusion

Despite the simplicity of its base equation, the Clapper-Yule model is one of the most accurate prediction models for halftone prints. Its main advantage compared to other models such as the Neugebauer model or the Yule-Nielsen-corrected Neugebauer model is the fact that physical parameters are attached to the different elements composing the print (inks, paper, and surface). The Fresnel terms can be adapted to the considered

measuring geometry, which is particularly interesting when predictions are made for a geometry different from the one used for calibration. The model also enables controlling ink thickness at printing time by comparing the colorant transmittances in various halftones, whose log is proportional to the ink thickness [5]. Recent improvements and extensions have been proposed which enable predicting both reflectance and transmittance of halftone prints thanks to extended flux transfer model relying on similar physical concepts as the Clapper-Yule model [6, 7].

Coefficient of Utilization, Lumen Method

Peter Thorns

Strategic Lighting Applications, Thorn Lighting Ltd, Durham, UK

Definition

The lumen method is an indoor lighting calculation methodology that allows a quick assessment of the number of luminaires necessary to achieve a given average illuminance level or alternatively the average illuminance level that will be achieved for a given number of luminaires. It is valid for empty rectangular rooms with simple three-surface diffuse reflectances for ceiling, wall, and floor.

Introduction

When an electric lamp is turned on, it emits light and it is possible to quantify the amount of light by measuring it, the result being given in the units of lumens. In itself this is a useful piece of information, but what would be more useful would be to have a method of converting this into a measure of the amount of light that would be received onto a desk from one or more luminaires or alternatively the number of luminaires necessary to achieve a given quantity of light on the desk. This calculation is known as the lumen method.

Light falling onto a surface is called illuminance and has units of lux (lx) or lumens per square meter (lm/m^2). It is not possible to see illuminance as light is actually invisible, which is fortunate, else any view would be degraded by looking through a fog of light. What is actually seen is the effect light has on surfaces, the reflected light, and this is called luminance with units of candelas per square meter (cd/m^2). To test this, place a sheet of white paper onto a dark surface (see Fig. 1). At the point where the edge of the paper meets the dark surface, the amount of light falling onto the two materials will be approximately the same. However, they appear completely different as the eye detects the light reflected back towards it, not the light falling onto the surfaces, and the white paper reflects more light than the dark desktop.

However, luminance is a difficult quantity to measure and changes with viewing position. Imagine a day-lit room with resultant shadows and patches of light reflected from polished surfaces. As the observer position moves within the space, the shadows and patches of light change with viewing position. As vision is essentially viewing luminance, this means that the luminance is view dependent. This makes it a difficult design quantity, so for ease, common practice is to design using illuminance which is view independent as

the amount of light falling onto a surface does not change with viewing position. (There are a few exceptions, an example being traffic routes, where design may use luminance, in this case the light that is reflected from the road surface).

Calculating the Maximum Achievable Illuminance

To be able to calculate the amount of light falling onto a surface from a given number of luminaires, it is necessary to be able to convert between the measures of lamp lumens (lm) and illuminance (lx). Remember lx is also lm/m^2 , so a given total quantity of lumens can be converted into illuminance by dividing it by the size of the area to be lit in m^2 . But it is important to consider where the area to be lit really is. Ideally luminaires should provide task lighting, that is, light the task being undertaken at any given point to the correct level of illuminance. This means that if there is a desk in a room, it would generally be lit to a level of 500 lx, the recommended level of illuminance for reading and writing tasks [4]. However, the circulation space within the room does not need this quantity of light, 200 lx being a perfectly adequate illuminance level to safely move around the space. This has two problems:

- Frequently in large spaces, it is not known where tasks such as desks will be positioned and may not be even clearly known what tasks will be performed within the space. Even if the task types and locations are known, most spaces and how they are used change through time. This means that, within reason, lighting has to be flexible enough to preserve the correct lighting conditions for changing requirements.
- Calculating the illuminance level for a particular area within a larger space is generally beyond the ability of a quick and easy calculation method. For lighting the calculation of an average illuminance across a space is relatively easy, while the calculation of the illuminance across a desk located in a room would normally

Coefficient of Utilization, Lumen Method,
Fig. 1 White paper on a black desk

require the use of a computer calculation program.

Therefore, to keep the calculation simple, it will calculate the average illuminance across a horizontal plane, called the task plane. This could either be the floor or a virtual plane at desk height depending upon the expected height of the task. So remembering the units of lm/m^2 , it is necessary to know the total quantity of lumens within the space. So

- For a given number of luminaires, N_{lum}
- Where each luminaire contains a given number of lamps, N_{lamp}
- And each lamp produces a given quantity of lumens, lm_{lamp}

the total amount of lumens available, lm_{total} , is equal to

$$\text{lm}_{\text{total}} = N_{\text{lum}} * N_{\text{lamp}} * \text{lm}_{\text{lamp}} \quad (1)$$

So for a given area of task plane, A_{tp} , and from Eq. 1, the known total amount of lumens available, lm_{total} , the absolute maximum illuminance possible, lx_{max} , will be

$$\text{lx}_{\text{max}} = \text{lm}_{\text{total}} / A_{\text{tp}} \quad (2)$$

There are two points to consider regarding the value produced by Eq. 2.

- This value assumes *all* the light produced by the lamps will be received onto the task, with no losses. This is generally not possible or even desirable.
- As this is the maximum illuminance theoretically (but not practically) achievable, if the illuminance is too low, at this point more luminaires and, hence more lumens, will be required.

So how is this result converted into a more practical value? The losses in light come from three main effects:

- Losses within the light fitting
- Losses through aging and dirt

- Losses through light not going directly to the task plane but via reflection from room surfaces

Accounting for Losses Within the Light Fitting

A luminaire is a housing containing a light source with associated control gear, optics, wiring, and electrical connections, both to the light source and to the external power supply. This creates a number of problems:

- The luminaire has its own microclimate, the temperature inside the fitting generally being different to that of the air outside. Designing a fitting so that the internal temperature is the optimum for the light source it contains requires skilled design, and the larger the difference between the optimum light source conditions and the actual luminaire conditions results in an increasing reduction in lumen output from the light source and/or reduced operating life expectancy for the source.
- An optic, no matter how well designed, has an element of inefficiency. No surface will reflect 100% of any light incident upon it and losses are cumulative. So, for example, if a metal reflector has a reflectance of 92%, then light that bounces once off the reflector before exiting the luminaire loses 8% of its initial lumens. If it requires two bounces to exit the fitting, only $0.92 * 0.92 = 0.85$ or 85% of the initial lumens exit the fitting, 15% being lost. Similarly optics that rely on transmission of light, such as diffusers or prismatic controllers, absorb some of the light, no material being 100% transmissive.
- Components within the luminaire will obstruct light, and this light may become trapped and never exit the fixture. For example, light emitted from the light source upwards into a ceiling recessed luminaire will need to be reflected around the light source, and some light will be lost in this process, trapped behind the source. (This can cause extra problems if the light is absorbed by the source, causing it to heat up further). Many reflectors trap light in

their back which may be open and shaped as the inside of a V with low reflectance.

Therefore, a measure is needed to quantify how all of these situations affect the lumen output of the luminaire. This is the light output ratio (LOR). Essentially the LOR is the ratio of light emitted from the luminaire to the light emitted by the light source, and the value of LOR is luminaire specific.

So to account for these effects, Eq. 2 is modified as shown in Eq. 3 below:

$$I_{x_{\text{luminaires}}} = I_{m_{\text{total}}} * \text{LOR} / A_{tp} \quad (3)$$

Accounting for Losses Through Aging and Dirt

When a lighting system is first installed, the lamps are new and all functioning, the luminaires are clean, and generally the room surfaces (floor, walls, and ceiling) are clean. However, through time the condition of the installation will deteriorate. As light sources age, their lumen output reduces (lumen depreciation) and some lamps will fail completely. Dust and dirt will gather on the reflecting surfaces of the luminaires, reducing how efficiently light is directed from the light source out of the fitting, and room surfaces will

become dirty and marked through everyday wear and tear. All of these will reduce the amount of light reaching the task plane.

A suitable maintenance routine, such as renewing aging lamps and cleaning the luminaires, will help minimize these impacts, but the amount of light received onto the task plane will still vary through life, reducing through time between maintenance cycles, increasing back to close to the original lighting levels immediately after a maintenance cycle (see Fig. 2).

However, a lighting design should be designed to produce a level of maintained illuminance, so that even at the point of maximum reduction in light just before maintenance is performed, the required light level is still achieved. To account for this, a maintenance factor (mf) is used, which is the amount of light lost when the light sources are at their oldest and the luminaires and room surfaces are at their dirtiest. So modifying Eq. 3 produces

$$I_{x_{mf}} = I_{m_{\text{total}}} * \text{LOR} * mf / A_{tp} \quad (4)$$

Further advice on the determination of maintenance factors is available from the Commission Internationale de L'Eclairage [3].

Coefficient of Utilization, Lumen Method, Fig. 2 A typical scheme maintenance cycle

Accounting for Reflection Losses from Room Surfaces

Equation 4 still makes one major assumption that all of the light from the luminaires goes directly onto the working plane.

However, this is rarely the case, light being directed onto the room surfaces (and it is rarely desirable for all light to go directly to the task as this would result in a pool of light within a dark room which would be an uncomfortable work environment). So some of the light hits the room surfaces (see Fig. 3), and some of this light will be reflected back onto the task (see Fig. 4). However, it should be remembered that no surface will have 100% reflectance. The quantity of light reflected will depend upon the material properties of a

surface, a light-colored wall typically having a reflectance in the region of 60%, so a quantity of light will be lost with each reflection from a surface. To account for this, a measure called the *utilization factor* (UF) is used. This is a measure of the total amount of light from a luminaire that reaches the task, both directly from the luminaire and indirectly through reflection from room surfaces. Manufacturers publish tables of utilization factors, and these vary as values are dependent upon the luminaire distribution, the room reflectance, and also upon the ratio of wall surface area to ceiling/floor surface area. (Given a ceiling with a high reflectance within a room that is tall and thin proportionally, there is a large amount of wall surface area to ceiling surface area, so the high reflectance ceiling will have less effect than for a

Coefficient of Utilization, Lumen Method,

Fig. 3 Light distribution onto the wall and floor

Coefficient of Utilization, Lumen Method,

Fig. 4 Light distribution from the wall to other room surfaces

large open plan office with a large ceiling surface area compared with the wall surface area).

To calculate the ratio of wall to ceiling/floor surface area, the room index (K) is used. This is defined as

$$K = (\text{area of ceiling} + \text{area of floor}) / \text{total area of wall}$$
(5)

For a room of length L, width W, and height H (where the height is the distance between the task plane and the luminaire plane, see Fig. 5), Eq. 5 becomes

$$K = ((L * W) + (L * W)) / (2(L * H) + 2(W * H))$$

Therefore,

$$K = 2(L * W) / 2H(L + W)$$

Therefore,

$$K = L * W / (L + W)H$$
(6)

So given the example table of utilization factors shown in Table 1, it can be seen that values of

utilization factor are supplied for a variety of room indices and surface reflectance's. From the table, it can be seen that for a room with reflectance's of

- Ceiling 70%
- Walls 50%
- Floor 20%

and with dimensions

- Length 12 m
- Width 12 m
- Height 3 m

which give a room index of

$$K = (12 * 12) / ((12 + 12) * 3) = 2$$

the utilization factor would be 0.69.

(Values used in the calculation are always percentages, so in this case, 69% = 0.69. Some tables may already show the values as fractions, in this case 0.69).

Therefore, using Eq. 4 adjusted by the utilization factor gives

Coefficient of Utilization, Lumen Method, Fig. 5 Room dimensions in terms of L, W, and H

Coefficient of Utilization, Lumen Method, Table 1 An example utilization factor table

Utilization Factors								
Room Reflectance	Room Index							
Ceiling/Walls/Floor	0.75	1.00	1.25	1.50	2.00	2.50	3.00	4.00
70/50/20	50	56	61	64	69	72	74	77
70/30/20	44	51	56	60	65	68	71	74
70/10/20	41	47	52	56	62	65	68	72
50/50/20	48	54	59	62	66	69	71	74
50/30/20	44	50	55	58	63	66	69	72
50/10/20	41	47	52	55	61	64	66	70
30/50/20	47	53	57	60	64	67	69	71
30/30/20	43	49	54	57	62	65	67	69
30/10/20	40	46	51	55	59	63	65	68
0/0/0	39	44	49	53	57	60	62	65

$$lx_{final} = lm_{total} * LOR * mf * UF / A_{tp} \quad (7)$$

So with knowledge of the type and number of luminaires in a space, it is possible to calculate approximately how much illumination the space will have.

Information on the calculation of utilization factor tables is available from the Commission Internationale de L'Eclairage [1, 2].

Calculating the Number of Luminaires Required in a Room

Equation 7 may also be rearranged to allow the calculation of the required number of luminaires to achieve a given illumination level.

$$lm_{total} = lx_{final} * A_{tp} / LOR * mf * UF \quad (8)$$

And using Eq. 1 gives

$$N_{lum} * N_{lamp} * lm_{lamp} = lx_{final} * A_{tp} / LOR * mf * UF$$

So the number of luminaires required to achieve a given level of illumination is

$$N_{lum} = lx_{final} * A_{tp} / LOR * mf * UF * N_{lamp} * lm_{lamp} \quad (9)$$

Definition

Visual search is a task requiring detection of one or more target items within a multi-item display populated by both target(s) and distractors.

Characteristics of the Visual Search Task

In a visual search task, the item that is being searched for is known as the **target**; other items are known as **distractors**. Figure 1 presents an example of visual search displays with one target item and a varying number of distractor items. Participant's task is to indicate whether a target is present or absent in the display, or to report an attribute of the target (e.g., whether it is on the left or right side). The total number of items in the display is known as the **set size**. Items in the search display can differ along various **feature dimensions**, for example, color or orientation. Individual items can take on different **feature values** from that dimension – for example, color (red or blue), or orientation (vertical or horizontal). If items in the visual search task vary along a

Color and Visual Search, Color Singletons, Fig. 1 Examples of visual search displays. A range of different set sizes is shown, going from 6 to 9 items. **(a)** Feature search: Target is a red circle. **(b)** Conjunction search: Target is a red vertical bar. Reaction time for each

set size is shown underneath each search set. Reaction times for feature search are typically independent of the set size, while reaction times for conjunction search most often increase linearly with the addition of extra items

single dimension, such as color, the observer is commonly asked to look for a target of a specified hue (e.g., red) in a set of distractors that differ in hue. This is known as **feature search**. In the case of feature search, distractors can be heterogeneous – all varying in hue – or homogeneous – all of them being of the same hue (e.g., blue, as in the example in Fig. 1a). If all distractors share the same color, the uniquely-colored target is defined as a **target singleton**. Note that **irrelevant singletons** are sometimes also used in visual search tasks, e.g., a single orange distractor can be introduced into a display with a red target and a number of otherwise blue distractors. Detection of color-singleton targets is very efficient, as long as there are no salient task irrelevant singletons. Such reaction times usually are independent of set size (see Fig. 1a). This is known as the **pop-out** effect characteristic of **parallel visual search**. If, however, items vary along multiple dimensions, the participant is commonly asked to look for, e.g., a red bar oriented upright among a set of distractors that differ in both hue and orientation (see Fig. 1b). This is known as **conjunction search**. Conjunction search is typically less efficient, producing reaction time costs as set size

increases, which is a characteristic of **serial visual search**.

Visual search: A Historical Overview

Visual search is one of the most commonly used tasks in attention research. The popularity of the visual search task stems from the fact that it operationalizes a vital activity performed by both humans and non-human animals. Eckstein's review [4] summarizes many examples of everyday search situations. In natural environments, foraging for food involves searching for edible fruit, while in man-made environments, operators monitor complex images in order to detect security-relevant or medically-relevant information. In many real world search situations, color is an important determinant of performance due to its ability to make certain features of the scene more or less conspicuous. For example, in order to avoid detection by predators, prey often adopts coloration that acts as camouflage, ensuring that it does not “pop-out” when seen in its natural environment.

Visual search became a prominent laboratory task for studying attention in the 1980s providing the initial evidence base for Treisman's highly influential Feature Integration Theory (FIT). FIT posits that attentional deployment is guided by multiple, distinct feature maps that can be activated in parallel [13]. Visual search represents an ideal task to test this theory, with the potential to reveal underlying neural representations of feature maps by using relatively simple, behavioral methods (for a review, see [10]). The slope of the reaction time (RT) function (milliseconds per item) was considered to be a particularly informative variable that provides insight into the amount of time required for an observer to process one item before moving on to the next item. In parallel search, the RT function slope is constant across various set sizes, which, according to FIT, is due to the target's unique representation in a retinotopic feature map activated in parallel to other basic-level maps. Color was shown to be one of the basic, pre-attentive features for visual search implying that it can be identified in parallel (i.e., without the deployment of serial attention) across the entire visual field. One of the most notable models of visual search to follow FIT is Wolfe's guided search model (for details, see [14]).

Determinants of Visual Search for Color

Color is considered one of the basic visual features since it can support parallel visual search. In fact, color has repeatedly been shown to be one of the most potent feature dimensions for guiding visual search (e.g., [1]). As long as the difference in chromaticity between the target and the distractors is sufficiently large, search for color is highly efficient and response times remain constant regardless of display density [9].

Clearly, proximity of items' chromaticity in color space is the key determinant of color search, with increased efficiency for targets that are closer to each other and further away from the distractors ([11]; see also [8] for converging evidence using a different experimental task). But what else affects search for color? Perhaps some of the low-level,

physiological signals are more salient than others? Alternatively, search could be more efficient for targets that are close to category prototypes. To answer this question, Lindsey et al. [7] contrasted contributions from cone-opponent, color-opponent or categorical representations when searching for a desaturated color singleton. They found that cone-opponent chromatic representations determined the speed of visual search, with bluish colors being particularly disadvantaged. At first, it may be surprising that low-level, cone-opponent representations enacted a more powerful influence on color search than higher-level, color-opponent or categorical representations. The two cone-opponent mechanisms can be mapped onto the two physiological pathways that extract chromatic signals: one distinguishes between reddish and greenish hues through opposing signals from L and M cones (L-M mechanism), while the other distinguishes between bluish and yellowish hues through opposing the S-cone signal and a combination of L and M cone signals (S-(L + M) mechanism). Lindsey et al. found that search was particularly ineffective when searching for desaturated (i.e., lighter) bluish colors, which were aligned with the bluish pole of the S-(L + M) mechanism. Meanwhile, search was particularly effective for pinkish colors, which fell in proximity of the reddish pole of the L-M mechanism. However, while the study by Lindsey and colleagues strongly suggests that cone-opponent signals are critical in driving search reaction times, the relation of such cone-opponent effects to the level of luminance contrast in the stimulus remains somewhat unclear. Li et al. [6] demonstrated that while search reaction times for targets defined by L-M contrast decrease after luminance signals are added, this is not the case for targets defined by S-cone contrast. Asymmetrical interactions between luminance and chromatic signals in determining target salience, especially as reflected in response speed, could provide a mechanism through which cone-opponent signals are able to influence visual search performance when searching for a desaturated target. However, relying solely on the visual search task to study representations that underlie attention to color may

be problematic as the task itself combines bottom-up, i.e., salience-driven, and top-down, i.e., goal-driven, influences on attention. A recent study by Ansorge and Becker [2] used a spatial cueing paradigm instead of the classical visual search in order to circumvent that problem, but the results failed to support a single representational space being employed for color selection.

During visual search, target features are maintained in working memory. This implies that visual search for color necessarily shares some constraints with working memory for color. Representations in working memory are impacted by color categories: they are significantly biased away from category boundaries and toward category centers [3]. These higher-level, category-driven computations may enact an important influence on search templates. In a similar vein, if targets and distractors can be distinguished on the basis of a relational criterion, e.g., “redder than” or “yellowier than,” absolute featural tuning gets overruled by such relational tuning. For example, in a study by Harris et al. [5] observers searched for orange among yellow distractors by selecting items that were “more reddish” when trials were blocked together. They tuned into orange as the particular feature only when the search displays of orange singletons among red distractors were randomly interleaved with search displays of orange singletons among yellow distractors, rendering such category-related, relational search templates ineffective.

Concluding Comments

Visual search experiments led to important discoveries on attentional selection of color. While visual search remains a highly useful task, it may be advantageous to consider the knowledge gained from visual search in a broader context: in recent years, foraging tasks yielded information on how we search for multiple targets that belong to different categories [15], while statistical summary representation tasks have been successfully used to measure attentional tuning into color [12].

Color Categorical Perception

J. Richard Hanley

Department of Psychology, University of Essex,
Colchester, UK

Definition

Categorical perception (CP) occurs when discrimination of items that cross category boundaries is faster or more accurate than discrimination of exemplars from the same category. Categorical perception of color is observed when, for example, a green stimulus and a blue stimulus are more easily distinguished than two stimuli from the same color category (e.g., two different shades of green). Color differences in terms of discriminability can be equated across between-category and within-category comparisons by using the *Commission Internationale de L'Eclairage* (CIE) values. It is therefore important to note that superior cross-category relative to within-category discrimination is observed when the physical distance between cross-category items and the physical distance between within-category items are equivalent.

Categorical Perception Using a Two Alternative Forced-Choice Procedure

Categorical perception of color has been demonstrated many times using a two alternative forced-choice (2-AFC) procedure. In an experiment of this kind, participants view a colored patch for a short duration. Shortly afterward, the original item is displayed next to a distractor, and the participant has to indicate which of the two colored patches was presented a few moments earlier. Discrimination between the target and distractor

is significantly more accurate when they belong to different color categories (e.g., green target and blue distractor) than when they come from within the same color category (e.g., target and distractor are different shades of green).

Categorical perception on the 2-AFC task has provided evidence for the existence of different color categories in different cultures [1]. For example, the Berinmo are a traditional hunter-gatherer culture in the upper Sepik region of Papua New Guinea who have a different set of basic color terms from speakers of English. Berinmo speakers showed significantly better discrimination of 32 cross-category items than 32 within-category items at the boundary between two Berinmo color categories (*nol* and *wor*) that do not exist for English speakers [1]. Conversely, English speakers did not show CP at this boundary. Most important, there was no evidence of CP at the boundary between green and blue for speakers of Berinmo whose language does not make this distinction. Such findings provide evidence against the idea that color categories are universal and exist irrespective of the color vocabulary that speakers have acquired during language development.

Hanley and Roberson [2] argued that CP in the 2-AFC task reflects the role of categorical codes in distinguishing targets from distractors. They proposed that, in principle, participants can perform the 2-AFC task using either categorical or perceptual information about the target item. The categorical code contains less information but may generally be easier to retain than the perceptual code. Targets and distractors can be more accurately distinguished when they cross a category boundary because they differ at both the categorical and the perceptual level. The categorical code cannot be used to distinguish targets and distractors from the same color category, however, so participants must rely entirely on the perceptual code. This account can readily explain the finding that CP for color was abolished when a verbal interference task was interposed between presentation of the target and the test pair [3]. Presumably, verbal interference disrupts participants' ability to generate or retain the category code, and so performance for both within- and

cross-category targets relied on retention of a perceptual representation of the color of the target.

Hanley and Roberson [2] also reanalyzed the results of a series of studies that had demonstrated CP effects for color using the 2-AFC task. This reanalysis revealed that within-category performance was particularly weak when the target was a poor example of a color category and the distractor was a better exemplar. If, however, the target was a good exemplar and the distractor a poor exemplar, performance on within-category trials and cross-category trials was equivalent. Such an outcome is of considerable theoretical importance because it challenges the commonly held view that CP has a perceptual basis (e.g., [4]). According to this account, CP occurs because perceptual systems are fine-tuned by experience such that sensitivity to change is greater around category boundaries than it is to changes that occur within a category. Exactly the same perceptual discriminations are required for within-category trials in which performance is good (central target, peripheral distractor) as for those in which performance is poor (peripheral target, central distractor). Consequently, the advantage for central targets over peripheral targets, which forms the basis for CP in the 2-AFC task, cannot reflect greater perceptual sensitivity for central targets.

Why is performance so poor on the 2-AFC task when targets are peripheral examples of a color category? Hanley and Roberson [2] argued that the poor exemplars in these studies were less likely to be classified as category members when they appeared at test alongside a good exemplar than when they appeared by themselves at presentation. The likely outcome is a mismatch between the way in which a peripheral target is categorized when it is originally presented and the way it is classified at test. A mismatch of this kind will lead to poor performance on the 2-AFC task because the categorical code now provides misleading information about the identity of the target color. This explanation is consistent with the findings that classification of an exemplar at the center of a color category was unaffected by the presence of a peripheral category member [5]. But, crucially, when a poor exemplar appeared alongside a

central exemplar, the poor exemplar was frequently assigned a different category label from the one it was given when it appeared on its own. Similar effects have been observed in other domains and have been termed “category contrast effects” [6].

Consistency of categorization is crucial to the account of CP for color in the 2-AFC task suggested by Hanley and Roberson [2]. For within-category pairs, it might appear that a categorical code could not possibly distinguish target from distractor. However, it follows from the category contrast effect that when the target is a central exemplar and the distractor is a poor exemplar, the distractor is likely to be given a different categorical label from the target. Hence, Hanley and Roberson argued that good performance in the 2-AFC task when the target is a central exemplar occurs because target and distractor can often be accurately distinguished on the basis of the categorical code. It also follows from the category contrast effect that performance will be poor on within-category trials when the target is a peripheral exemplar. For example, a greenish-blue boundary target may be categorized as “blue” when it appears on its own. However, the presence at test of a distractor that is a good example of “blue” means that the peripheral “blue” target will sometimes elicit a different category label (“green”) at test. The outcome will be that the category label given to the target at encoding is elicited at test only by the distractor, which is likely to be selected in preference to the target as a consequence.

Categorical Perception in Visual Search Tasks

Even though test stimuli are presented relatively soon after the target has been removed, performance on the 2-AFC task necessarily depends on a memory code for the target color. Recent studies have also found CP for color in visual processing tasks where the memory component is minimized. For example, Gilbert et al. [7] presented an oddball stimulus in the presence of a series of

identically colored background items. Even though the size of the physical difference between the oddball and the background items was held constant, participants were quicker to identify the oddball when the background items belonged to a different color category from the oddball than when oddball and targets were different exemplars of the same color category. Brown et al. [8] have failed to replicate these findings and claim that color discrimination on this task is determined by perceptual rather than categorical differences. Nevertheless, similar results to those reported by Gilbert et al. [7] have been reported in several studies [9–11]. For example, Franklin et al. [10] adapted the task by presenting participants with a colored background and asking them to indicate as quickly as possible which side of fixation a differently colored patch suddenly appeared against this background. Response times were significantly faster when background color and patch came from different categories than when the patch and background were different exemplars of the same category.

In some languages such as Russian, Greek, and Korean, additional color categories exist that are not present in English. For example, *siniy* (dark blue) and *goluboy* (light blue) are distinct basic color terms for speakers of Russian, and *yeondu* (yellow-green) and *chorok* (green) are distinct basic color terms for speakers of Korean. An important question is whether CP can be observed in visual search tasks at boundaries between color categories of this kind. This issue has recently been investigated with speakers of Russian [11] and with speakers of Korean [9]. Russian participants showed CP at the boundary between *siniy* and *goluboy* in the visual search task [11]. Conversely, English speakers, who would call all of these stimuli “blue,” did not show the same cross-category advantage at the *siniy*-*goluboy* boundary. Korean participants showed CP at the boundary between *yeondu* and *chorok*, but no evidence of CP was shown by native English speakers at this boundary [9]. These findings reinforce the claim that color categories are determined by the color vocabulary that speakers acquire during language development.

Two sets of additional findings have provided information about the precise point at which categorical codes influence color categorization in this experimental paradigm. First, CP was not observed in perceptual tasks when participants carried out a concurrent verbal interference task [7, 11]; under verbal suppression, all equally spaced separations of color were equally easy to discriminate regardless of the presence of a color boundary. Second, Gilbert et al. [7] and Roberson et al. [9] reported that the CP effect was only found for colors that were presented in the right visual field, which is presumed to preferentially access language-processing areas in the left hemisphere. No difference between within-category and between-category pairings of targets and distractors was observed for colors presented in the left visual field, which gains preferential access to the nonverbal right hemisphere. Gilbert et al. [7] also showed that CP was found only when stimuli were presented to the left hemisphere of a patient in whom the corpus callosum (the structure that connects the two hemispheres of the brain) had been surgically severed.

The speed with which categorical information is accessed in these visual processing tasks suggests that there is rapid automatic retrieval of a categorical code when a colored stimulus is presented. Nevertheless, the results from these tasks can be readily explained in terms of Hanley and Roberson's [3] dual code account of categorical perception. Assume that decisions about whether a target and a background item are the same color are taken on the basis of either a right hemisphere perceptual code or a left-hemisphere categorical code and that when the two codes conflict, accuracy and speed will be reduced. Automatic activation of color category names should therefore slow judgments about whether, for example, two different shades of blue are different. This is because the categorical information that they are the same is in conflict with the perceptual information that they are different. Decisions for items from different categories (e.g., blue and green) will be quicker and more accurate because both the categorical and perceptual codes provide evidence that is consistent. When the left-hemisphere

language system is suppressed by verbal interference, or is not accessed because information is presented directly to the right hemisphere, the categorical code is not generated, and there is never any source of conflict with the perceptual code. Hence, without the language system, there is no advantage for comparisons that fall across category boundaries. Such an account can also explain why an unpredicted improvement in within-category performance has been observed when verbal interference abolished CP for color [7, 11]. Within-category performance cannot be delayed by a mismatch between the categorical and perceptual codes if a categorical code is not generated.

Categorical Perception and Event Related Potentials (ERPs)

Categorical effects for color have also been demonstrated in a paradigm that measures event-related potentials [12]. Participants were asked to look at a display containing a series of colored patches and respond as soon as they saw a cartoon character that appeared infrequently among the patches. The key manipulation was that the patches changed color; sometimes the color category changed, and sometimes the shade changed but the color category remained the same. These color changes took place at a different time from the appearance of the cartoon figures. Color processing was incidental because participants were never asked to pay any attention to color when making their responses to the appearance of the cartoon figures. The latency of the response in the ERP signal to cross- versus within-category color changes was investigated. Crucially, significantly earlier ERP peak latencies were observed when the color change involved a different color category (195 ms) than when the change involved a different exemplar from the same color category (214 ms). Such findings make it clear that information about color categories is available within the brain at a very early stage of visual processing.

Thierry et al. [13] employed a similar task to native Greek speakers. The Greek language

makes a categorical distinction between light blue (*ghalazio*) and dark blue (*ble*). Thierry et al. investigated the strength of the ERP response to unexpected changes from *ble* to *ghalazio* and reported a difference in the amplitude of the ERP. They referred to the response to such changes as a visual mismatch negativity effect (VMMN). The Greek speakers' ERP responses were significantly weaker when there was an unexpected change from light to dark green that did not cross a category boundary for either Greek or English speakers. Conversely, speakers of English did not show a stronger VMMN response to changes from *ble* to *ghalazio* than to changes from light to dark green. Athanasopoulos et al. [14] subsequently found that the signal strength of the VMMN response shown by their Greek participants when *ble* changed to *ghalazio* was negatively correlated with their length of stay in the UK. Once again, these findings emphasize the close link between visual processing of color categories and participants' linguistic experience.

Mo, Xu, Kay, and Tan [15] investigated the strength of the VMMN effect when the color change occurred in only the right (RVF) or in only the left visual field (LVF). They reported significant VMMN effects in both hemifields. Like Thierry et al. [13], Mo et al. found a stronger VMMN when a color change crossed a category boundary (in this case the boundary between blue and green) than when there was a change between two equally distinct exemplars of the same color category (e.g., different shades of green). Crucially, however, this categorical effect was observed only when the color change occurred in RVF; in LVF the strength of the VMMN was equivalent for within- and between-category changes.

In the ERP data, differential responses to cross-versus within-category pairs of stimuli appear between 100 and 300 ms after stimulus presentation. Such rapid processing of categorical information has led to suggestions that CP in perceptual tasks of this kind may reflect activity at a site in visual cortex rather than in language areas [12]. These findings are clearly consistent with the claim that CP effects for color can

sometimes be genuinely perceptual and may arise from increased perceptual sensitivity at color category boundaries. It is, however, difficult to reconcile this claim with the finding that even the early and automatic categorical color effects that are detected by ERPs are lateralized to the left cerebral hemisphere [15]. Furthermore, the published studies that employ these ERP tasks have, to date, only reported cross-category versus within-category contrasts. Exactly the same perceptual discriminations are required regardless of whether the color change on within-category trials is from a good category member to a peripheral category member or vice versa. It remains to be seen whether the ERP signal is equally weak in both these situations relative to the ERP signal generated by a color change that crosses a category boundary. It is therefore unclear whether the asymmetry of within-category performance found consistently to cause CP in 2-AFC tasks [2] generalizes to visual mismatch negativity in ERP signals. If color CP effects in these visual processing tasks are also the result of a category contrast effect, it would be difficult to see how an explanation of the ERP data that is based on perceptual sensitivity could reasonably be maintained.

Definition

Natural language is full of vagueness. Some people are definitely tall, others are definitely *not* tall, but there are also people who possess the property of tallness only to some intermediate degree. While colors are paradigmatic examples of properties that objects may possess to some intermediate degree, most of the work on color categorization has almost completely ignored the issue of vagueness. The issue has been addressed in more recent research, however, and this research has also contributed to our general understanding of vagueness.

The Metaphysics of Color Categories, Their Prototypes, and Their Boundaries

We carve up reality into different categories for both intellectual and practical reasons: being able to differentiate among the many objects we encounter facilitates learning, memorization, prediction, and action. There is an ongoing debate about the metaphysical status of those categories. Do they reflect fundamental building blocks of the world – at least ideally, leaving open the possibility that our *current* categories fall short of meeting that ideal – or are they merely conventional, and would other ways of carving up reality have served us just as well? In the former case, categories would be universal, at least under ideal circumstances; in the latter case, one would expect them to be relative to culture.

In philosophy and beyond, there has been much a priori speculation about the universalism–relativism issue. Twentieth-century color research, in particular the work on color naming initiated by Berlin and Kay [1], provided important *empirical* input to the debate (→ “► [Berlin and Kay Theory](#)”; → “► [Color Categorization: Patterns and Mechanisms of Evolution](#)”). And while there was evidence in Berlin and Kay’s data for there being conventional aspects to color categorization (→ “► [Cross-cultural Communication](#)”), the preponderance of evidence was in favor of a universalist conception of color categorization, leading Berlin and Kay to posit the existence of so-called basic color categories (BCCs). Thereby, their findings were also at least partial evidence for universalism vis-à-vis categorization more generally.

Related to the debate about the metaphysical status of categories has been a debate about prototypes, which are generally understood as being the categories’ most typical representants. Might these be best thought of as being conventionally determined – perhaps depending on which instances we have most frequently, or most recently, encountered – or are they also part of the blueprint of reality [2, 3]? Note that this issue is to some extent orthogonal to the question of the status of categories: even if the categories are universal, the choice of which instances best represent those categories might be entirely up to us, so that different cultures with a shared system of categories might still identify different instances as being prototypical for those categories. Here, too, Berlin and Kay’s work provided empirical support for a universalist position, at least in the domain of color.

More recently, the empirical results have been buttressed by various results coming out of a computational modeling approach to categorization, especially color categorization (→ “► [Color Category Learning in Naming-Game Simulations](#)”). The most notable results to date were obtained in important work by Regier and colleagues [4], who – following an idea from Jameson and D’Andrade [5] – implemented a number of general information-theoretic principles in an optimization algorithm. Specifically, Regier and

colleagues placed the 330 color chips that Berlin, Kay, and their collaborators had used (→ “► [World Color Survey](#)”) in CIELAB space (→ “► [CIE 1931 and 1964 Standard Colorimetric Observers: History, Data, and Recent Assessments](#)”; → “► [Psychological Color Space and Color Terms](#)”) and let a computer divide those chips into 3, 4, 5, and 6 categories, subject to the constraint that the resulting system should maximize similarity of the colors within each category while also minimizing similarity of the colors across the different categories, where similarity was defined in terms of closeness in CIELAB space. Regier and colleagues were thus able to recover computationally many of the color categorizations that Berlin, Kay, and their collaborators had found in their field work.

However important the aforementioned research is, it can easily leave one with a wrong idea about the *boundaries* of color categories. In standard ways of presenting results concerning color categories, these categories almost invariably have *sharp* boundaries, as if there were regions in color space such that, for instance, any shade represented by a point in that region is definitely orange while any shade represented by a point outside that region is definitely not orange. That color categories are so sharply delineated from one another may be a convenient assumption for a variety of purposes, but there can be no question that it is false. Most drawing software allows one to pick a color and then gradually change its coordinates (typically, its RGB coordinates). Assuming we have access to such software, we can, for example, start with a clear shade of red, then adjust the color coordinates little by little such that the shades we are seeing gradually become more orangish, until we arrive at a shade that we would designate as being clearly orange. The shades we saw in the process, which can be thought of describing a path through color space, will certainly not all have been clearly identifiable as red or clearly identifiable as orange. Many will have been somehow in-between those colors; their color will have been *vague*.

Though it is evident, at least upon reflection, that color categories have vague rather than sharp boundaries, and that hence predicates like “red”

and “blue” sometimes apply only to some intermediate degree, the study of the issue of vagueness in relation to color is badly neglected. One reason for this may be that the issue of vagueness itself is a can of worms, with linguists, logicians, and philosophers having proposed a number of ways of dealing with vagueness, none of which has been able to garner widespread support.

Language, Logic, and Vagueness

Modern logic was developed to facilitate mathematical reasoning. As such, it has been immensely successful. But in a number of respects, the language of mathematics is special. Most notably, there are no vague mathematical expressions. That is a problem if we seek to extend the scope of logic to natural language. In standard logic, there is the law of excluded middle, which implies that for any predicate P and any constant c , $P(c)$ is either true or false. But for many ordinary language predicates, that law appears to fail. As mentioned, for instance, there are people we deem neither definitely tall nor definitely not tall, and similarly for many color shades, which we do not deem to fall squarely into any one color category. In the literature on vagueness, such cases are referred to as *borderline cases*.

Logicians have responded to this problem in two ways: (i) deny the existence of vagueness, and (ii) revise logic. The first response [6] asserts that, for any seemingly vague predicate, there is actually a precise cut-off point, delineating the items to which the predicate applies from those to which it does not apply. In this view, vagueness is not really a metaphysical problem but only an epistemic problem. It is an expression of our ignorance, stemming from our limited discriminatory capacities, and not a feature of the world.

The second response comes in a variety of flavors. Some have proposed to admit a third truth value, which is then to indicate something like indeterminacy. Others have wanted to go beyond this, by admitting *many* intermediate truth values, possibly even *infinitely* many. (See the papers in [7] for useful discussion of the various options.)

While none of these proposals could be said to be popular, there is a proposal for revising semantics – roughly understood as a theory of assigning truth values to sentences, which is an important part of logic – that has recently received some empirical support. Kamp and Partee [8] consider a language that contains both vague and nonvague predicates and show how one can obtain a unified semantics for that language. One of the cornerstones of their proposal is the notion of a *completion*, which is a way of resolving vagueness by arbitrarily choosing, for any vague predicate P , a cut-off point such that some of the borderline P cases are counted as being definitely P while the remaining borderline cases are counted as being definitely *not* P . While the cut-off point is arbitrary, it should still be the case that if a borderline P case a is counted as being definitely P , then any borderline case b that is at least as P (at least as tall, green, or whatever P stands for) as a should also be counted as being definitely P .

The second cornerstone of Kamp and Partee’s proposal is the notion of *graded membership*, which they define in terms of completions. Suppose a simple case in which there are only finitely many completions, that is, finitely many ways of splitting up the borderline cases such that the aforementioned constraint (if a is definitely P then anything at least as P as a is definitely P as well) is met. Then for any borderline P case a , we can take the proportion of completions that group a with P as measuring the degree to which a is P . If there are infinitely many completions, then the idea is the same, although the implementation requires the help of measure theory.

Kamp and Partee’s proposal had some loose ends. It turned out, however, that the remaining problems could be easily solved by embedding their proposal in a conceptual spaces framework [9]. Doing so has the additional advantage of making the proposal testable. Color space being one of the most readily available conceptual spaces (e.g., CIELAB and CIELUV space are accessible via a number of widely used software packages; → “► [CIE u', v' Uniform Chromaticity Scale Diagram and CIELUV Color Space](#)”), it is unsurprising that some of the testing has taken place in the color domain.

Predicting the Vagueness of Color Shades

Conceptual spaces are built on top of similarity spaces, which are one- or multidimensional metric spaces in which distances measure dissimilarities [10]. The further apart two points are in a similarity space, the more the items mapped onto those points are dissimilar in the respect represented by the space. Using as an example some color similarity space (e.g., CIELAB or CIELUV space), the closer two points are in this space, the more similar in color are items mapped onto these points [11].

To obtain a conceptual space from a similarity space, we add a structure to the latter that carves it up into regions, where these regions are then taken to represent concepts, generally understood as the mental correlates of linguistic expressions. For example, a conceptual color space is a carving up of CIELAB or CIELUV space, or possibly some other color similarity space, into a number of regions, with the various regions representing color concepts. In this picture, the concept of redness can be thought of as a region in CIELAB or CIELUV space, and as can for the concepts of blueness, greenness, and so on.

A popular way of arriving at such a carving-up uses the mathematical technique of *Voronoi tessellations*. A Voronoi tessellation starts with a set of *generator points* in a similarity space, and then divides that space into as many cells as there are such points, following the principle that, for any cell, all points lying in the cell should be at least as close to the generator point associated with that cell as they are to any of the other generator points. A natural choice of generator points in the context of conceptual spaces has been prototypes. For instance, to arrive at a conceptual color space, we might determine the locations of the BCC prototypes in, say, CIELAB space and then let these serve as generator points for a Voronoi tessellation of that space. See the left panel of Fig. 1 for an illustration.

The tessellations resulting from this kind of operation are known to have various attractive features from a cognitive point of view [10]. Depending on the concepts one wants to represent, however, a drawback can be that this type of tessellation makes the boundaries between concepts *sharp*. For color concepts, the drawback is particularly evident, for a reason already mentioned: if we traverse CIELAB or CIELUV space,

Color Categories and Vagueness, Fig. 1 Left: A Voronoi tessellation of a two-dimensional space, the points representing the prototypes and the lines showing the borders between the categories. Right: A collated

Voronoi tessellation, equipped with prototypical regions instead of prototypical points, and having thick boundary regions instead of sharp borders between categories

we do not find the abrupt transitions between, for instance, red and orange that are suggested by a Voronoi tessellation of those spaces obtained in the way just described. Instead, we find gradual transitions; for instance, traveling from clearly red to clearly orange, we go through various stages of borderline red-orange.

To solve this problem, Decock and Douven [9] draw on *collated* Voronoi tessellations, which pack together bundles of (single) Voronoi tessellations, melding them into one tessellation [11]. This leads to concepts being separated from one another by boundary *regions* rather than boundary *lines*. Their proposal is to first do away with the fiction that concepts always have a singular prototype (e.g., there are many shades of red that people deem typically red, as is also attested by empirical research [1, 3]) and rather recognize that, at least for many concepts, we can discern *regions* in a conceptual space where their prototypical items are represented. Then a collated Voronoi tessellation is constructed by conjoining all ordinary Voronoi tessellations that are generated by a set of points consisting of one from each prototypical region. These have boundary regions which meet a number of important desiderata

[12]. See the right panel of Fig. 1 for an illustration.

The final step in Decock and Douven's proposal is to connect the idea of conceptual spaces equipped with a collated Voronoi tessellation with Kamp and Partee's semantics for languages with vague terms. The main bridge between the two lies in the observation that the single Voronoi tessellations that make up a collated tessellation can be regarded as the correlates in the conceptual spaces framework of Kamp and Partee's completions: each such single tessellation is a way of grouping items in the boundary region of a concept with either the clear instances of that concept or its clear non-instances, and – because of the metric structure of the space – it does so in a way that satisfies Kamp and Partee's constraint on completions.

An immediate empirical consequence of this is that degrees of membership of any item representable in a space can be calculated from the structure of the space together with the locations in the space of the prototypical regions of the concepts it represents. For instance, given that the structure of the main color similarity spaces is known, knowledge of where in those space the regions

Color Categories and Vagueness, Fig. 2 CIELUV space with the prototypical regions for blue and green, and with three series of shades all going from clearly blue to clearly green. The highlighted points are shades for which researchers ([13]) calculated the degree of blueness and degree of greenness, which they then compared with

human judgments. (To give an impression of the global shape of CIELUV space, the figures also show thinly the set of 1625 Munsell chips available from the website of the Program of Color Science, Munsell Color Science Laboratory, Rochester Institute of Technology)

representing the prototypical red shades, the prototypical orange shades, and so on, are located allows one to calculate, for any point in the space, the degree to which the shade corresponding to that point is red, orange, blue, green, and so on.

There is recent empirical evidence that bears out the predictions flowing from the above proposal. Specifically, researchers [13] gathered information about the locations of the prototypical regions for blue and green in CIELUV space; see Fig. 2. They then calculated, for various shades in the blue-green region of that space, also shown in the figure, the degree to which they were green and the degree to which they were blue, according to Kamp and Partee's semantics as embedded in the conceptual spaces framework. The predictions turned out to be highly accurate, thereby buttressing that semantics and making a strong empirical case for a particular account of vagueness.

Color Categorization and Naming in Inherited Color Vision Deficiencies

Valerie Bonnardel
Psychology, University of Winchester,
Winchester, UK

Synonyms

[Dichromat color naming](#)

Definition

Color categorization and naming behaviors of human observers that experience forms of color vision deficiency called “dichromacy.” Such deficiencies are sex linked and predominantly affect males and are due to errors in photopigment expression or functioning or to the failure to inherit the genetic precursors for the expression of a normal set of retinal photopigments.

Color Naming and Categorization in Color Deficients

Human color perception is categorical. Light diffracted through a prism provides a visible spectrum spanning continuously from 400 to 700 nm in the wavelength interval that readily appears to the human eye as a smooth juxtaposition of colored bands of different width. By adding to the visible spectrum a mixture of spectral lights, Isaac Newton described a color circle with its different sectors as *violet*, *indigo*, *blue*, *green*, *yellow*, *orange*, and *red* (Fig. 1) [1]. For the great majority of the Caucasian population (96%), Newton’s

seven-color categories (although not unanimously agreed upon) are a fair account of human color experience. However, for a substantial percentage of men who are color deficient (8%), this description is inadequate. Compared to individuals with normal color vision, color deficient have reduced color discrimination abilities and live in a linguistic environment with a larger color vocabulary than the gamut of color percepts they probably experience. Yet, in everyday life, color deficient’s use of color names permits intelligible use of color in conversation, and their deficiency is largely unnoticeable by color normal interlocutors. As such, color deficiencies offer a useful paradigm for the study of the complex relationships between idiosyncratic perceptual experience and its linguistic expression.

Color Vision Deficiencies

Only inherited forms of color vision deficiency associated with changes in the genes on the X-chromosomes will be considered here. Normal color vision is trichromatic and results from light absorption by three different types of photopigments located in the retinal cell receptors called “cones.” Short-wavelength (SW), medium-wavelength (MW), and long-wavelength (LW) cone photopigments absorb light maximally in short (440 nm), medium (540 nm), and long (560 nm) wavelengths. A genetic polymorphism affecting X-linked genes encoding for MW and LW cone photopigments induces small variations in their absorption peak, leading to subtle variations among normal trichromats; larger variations produce deficiencies. In the extreme case, a gene deletion occurs, and as a result, color vision will lose one dimension and will be dichromatic. A more moderate condition arises from gene alterations that generate hybrid photopigments. In this case, color vision is referred to as anomalous trichromatic. When LW photopigment is affected, deficiencies are of the protan type, with about 1% of dichromats (of “protanope” type) and 1% of anomalous trichromats or “protanomalous.” When the MW photopigment is concerned, deficiencies are of deutan type and account for frequencies of 1.4% “deuteranope” and 4.6% of “deuteranomaly.”

Color Categorization and Naming in Inherited Color Vision Deficiencies, Fig. 1 Color circle from Newton’s Opticks [1]. (Source: <http://posner.library.cmu.edu/Posner/books/>)

In practice, color deficient people confuse colors that are easily discriminable to normal trichromats. To gain intuition on color deficient's perceptual experience, two clarifications are useful to bear in mind. The first consists in defining the term "color" which can be polysemous. Color can be defined as corresponding to the appearance of objects and lights resulting from the combination of three perceptual attributes associated to three physical variables, that is, "hue" (associated to dominant or complementary wavelength), saturation (associated to purity), and brightness (associated to luminance). Color deficient people primarily confuse hues and retain the ability to discriminate between different levels of saturation and brightness. Secondly, photoreceptor absorption process is not useful when considering the perceptual implications of their dysfunction. This is better accounted for by considering further stages of color processing which involve synergic and antagonist neural linkages between photoreceptors to form an achromatic (white vs. black) [MW+LW] and two-chromatic channels: "red" versus "green" [LW-MW] and "yellow" versus "blue" [(LW+MW) – SW]. Dichromats who are missing either LW or MW photoreceptors are assumed to retain a single color-opponent channel: [MW-SW] or [LW-SW] (protanope or deuteranope, respectively). Anomalous trichromats possess a residual yet functional "red-green" [LW-MW] channel. Considering the diversity of

anomalous trichromat types, illustrations of color deficiencies will be limited to dichromatic vision.

Algorithms based on the reduction assumption permit dichromatic color gamut simulations as seen by individuals with normal color vision [2]. The simulated color circles for deuteranope and protanope are filled with blue, yellow, and shades of those colors and a neutral or achromatic zone (Fig. 2). Although the qualities of another person's sensations can never be fully known, such simulations provide insights on magnitudes of the difference that might exist between dichromatic and trichromatic color experience.

Despite substantial differences in color experience, the condition of color deficiency had not been reported until the end of the eighteenth century. John Dalton (posthumously diagnosed in 1995 as a deuteranope by means of molecular genetic techniques [3]) provided the most comprehensive description of color deficiency based on his own experience. It is at age of 28, when noticing that a geranium changed its color from sky blue in daylight to yellowish in candlelight, that Dalton suspected his color vision to be different from that of others. From systematic observations of the solar spectrum, Dalton established that if people distinguished six color categories, namely, *red*, *orange*, *yellow*, *green*, *blue*, and *purple* (further divided in *blue* and *indigo* to fit with Newton's nomenclature), he was able to see only two or at most three distinctions: *yellow* and *blue*

Color Categorization and Naming in Inherited Color Vision Deficiencies, Fig. 2 Color circle obtained from sRGB color display (center) and its two simulations as

supposedly seen by a deuteranope (left) and protanope (right). Simulations were obtained with Vischeck (www.vischeck.com)

or *yellow*, *blue*, and *purple*. This description is in fair agreement with today simulations presented in Fig. 2.

Dichromats Color Naming and Categorization Abilities

In everyday life, colors are usually object colors, and as young children, dichromats can learn to associate color names with objects of pre-determined color such as green grass or red cherries, and it is not surprising that dichromats use “red” and “green” to refer to colors that seem so distinctive to others. However, “red” and “green” are also used accurately most of the time for non-predetermined object colors such as clothes or furnishings, and asking color names to color deficient gives little indication of a color perception deficiency. It is in laboratory situation that one can measure the discrepancy between perception and naming in dichromats. Jameson and Hurvich [4] in an article entitled “Dichromatic color language: “reds” and “greens” don’t look alike but their colors do” [4] reported an experiment using arrangement color tests (i.e., Farnsworth D-15, with 15 colors), where colors printed on small caps should be ordered by perceived similarity. In this type of tests, dichromats make systematic and identifiable color alternations from which color diagnosis is based. For instance, dichromats put cap #2, considered by normal trichromats as “blue-green,” next to cap #13, a “violet-blue” cap. When subsequently, dichromatic observers were asked to name the same stimuli, the authors noted several interesting observations. Firstly, and despite confusing their colors, all dichromats used “red” and “green” words. Secondly, a dichromat could describe a color cap as “red-green.” This designation never occurs in normal trichromat observer as, due to their antagonist nature, these percepts are mutually exclusive. Thirdly, a large interindividual variation was reported among dichromats. For the less keen observers, “red”-“green” were used indifferently to refer to colors seen as red or

green by normal trichromats. Yet, some dichromats were able to produce a naming pattern indistinguishable from that of a normal trichromat, thus revealing a gap between perceived similarity and naming. For instance, if cap #2 was placed next to cap #13 in the arrangement test, in agreement with normal trichromat, cap #2 was named “blue-light” and cap #13 “reddish blue.” In this experiment, correct naming was explained by subtle luminance differences between red and green caps that could have been used by dichromats. To the careful dichromatic observer, the simple rule “darker, then red” provides a better-than-chance correct naming.

This rule would be more difficult to apply when colors are shown in isolation. This setup was used in an experiment with 140 Munsell color samples varying in hue, saturation, and brightness intended to probe naming and categorization. In the naming task, participants had to choose one of the eight chromatic basic color terms (BCT, namely, *red*, *green*, *blue*, *yellow*, *orange*, *pink*, *purple*, and *brown*) to describe each sample presented in isolation. Categories thus obtained for the two dichromats tested were very similar to normal trichromatic prototypical naming categories, with 66% and 72% of the samples described with the same BCT as used by normal trichromats. In the categorization task, color samples were sorted in eight categories based on their perceptual similarity with, this time, the overall sample collection displayed on a large table, inciting comparison strategy. Despite the possibility of samples’ visual comparison, local category inversions corresponding to cases where stimuli were assigned to groups in a way that is contrary to the structure of the nearest neighbor were observed in the categorization task, while absent in the naming task. Moreover, for the same number of categories, color naming produced a more consensual categorization pattern compared to perceptual similarity. Indeed, color names that define category boundaries in terms of hue (i.e., red, green, blue, yellow, orange, and purple), saturation (i.e., pink), and brightness (i.e., brown) further constrain the elicited

categories by, for instance, excluding categories such as turquoise or pastel that would be legitimate based on similarity criteria. This added constraint in normal trichromats increased the consensus between participants from 72% (categorization task) to 82% (naming task) and similarly from 66% to 76% in color deficient [5]. Language appears to operate normalization effect on categories obtained by naming in color deficient, yet it does not seem to be readily available to fine-tune color categories when these are based on perceptual similarities.

Explanations for Dichromat Color Naming and Categorization Abilities

Aside from subtle luminance differences or lightness cues, dichromat color naming and categorization performances have been explained by the contribution of other visual signals. In particular, rods distributed in peripheral retina and absent from the fovea are mediating low-light intensity vision and can act as a third photoreceptor. Under moderate light conditions, for surfaces larger than 4° of visual angle or presented in periphery, dichromats reveal trichromatic color matches comparable to normal trichromats' small-field (2°) color match, that is, for these larger field sizes, they need two primary lights (red and green) to match a spectral yellow light. Under these conditions, dichromat large-field trichromacy is explained by rod-cone interaction providing a residual red-green sensitivity [6]. In the naming of 424 OSA Uniform Scales samples presented in isolation, dichromats produced trichromat-like responses in conditions where rod-cone interactions were possible. When rod contribution was excluded by bleaching the photopigment by light preexposure, trichromat-like naming was no longer possible in the red-green dimension [7].

Dichromats still perform better than expected on perceptual tasks in conditions where luminance and rod-cone interaction are ruled out. For instance, in hue-scaling experiment, stimuli were monochromatic lights presented in a 2° field. Observers' task consisted in describing each

stimulus by a given proportion of "yellow," "blue," "red," and "green." In this experiment, a molecular genetic analysis had confirmed that dichromat participants had only one functional X-chromosome-linked photopigment opsin gene (either L or M), excluding the possible contribution of a residual red-green color vision. Dichromats reported the presence of a red component in the 420–450 nm interval and explicitly referred to blue and red mixture. These data suggest a dichromatic color space structure is richer than that illustrated by simulations based on linear model and reduction assumption as presented in Fig. 2. A model including a nonlinear transfer function of signals from S and L or M cones can account for a richer dichromatic perceptual space with enhanced naming and categorization abilities [8].

Non-chromatic visual cues, rod-cone interaction, or nonlinear transfer function could all provide supplementary visual information to dichromats to resolve ambiguities in an otherwise impoverished chromatic environment. However, color naming shows a more trichromat-like pattern than similarity or perceptual categorization tasks can elicit. The comparison between colors and color-naming structures has been addressed in similarity tasks using color cards and their corresponding color names printed on cards. Similarity judgments were requested for 36 pairs of stimuli. Apart from a violet-blue inversion, the multidimensional scaling analysis of dichromat color name data provided a Newton color circle in a two-dimensional model with yellow-blue and red-green axis. For color similarities, the color circle was distorted along the red-green axis, bringing these two colors next to each other [9].

Dichromats have correctly learned the relational structure between color names as established by normal trichromats. Yet, as noted by Jameson and Hurvich [4], a dichromat's correct conceptual representation of color is not used to optimize performance on perceptual tasks. This finding indicates that the existence of an isomorphism between percept and concept structures is not compulsory; each type of representation coexists with no apparent conflict and can be used independently to fulfill specific task demands.

Definition

Color categories are mental constructs that partition the gamut of all colors, perceived by an individual, into a number of discrete entities, each labeled with a color name [1, 2] (► [“Color Categorical Perception”](#)). In anthropologic and psycholinguistic studies, a color category/name is defined in terms of its objective referents, or denotata, i.e., a range of color samples it encompasses. The referents are either standardized color chips, such as those constituting Munsell charts (► [“World Color Survey”](#)), or color stimuli whose hue, brightness/lightness, and saturation are specified in photometric terms (e.g., CIE x y z , CIELUV, CIELAB, etc.) [3] (► [“CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength”](#)). The volume of color categories and the boundaries that demarcate them manifest by consensus across the speakers of a language, facilitating effective communication (► [“Psychological Color Space and Color Terms”](#)). Beyond the denotative function, in linguistics, and, in particular, in linguistic pragmatics, the meaning of a color term is defined by its referential meaning, or use patterns, such as frequency of use, immediacy of response, collocations, and connotations, which reflect the term's affective values, cultural conventions, semiotics, and social-marker functions [4].

The Universalism Versus Relativism Debate

Until late 1960s, dominant was the *relativist view* (aka the Sapir-Whorf hypothesis) on color categories in individual languages. According to it, languages mark off different parts of the color continuum quite arbitrarily, implying that color names of different languages do not embrace the same denotative entities, and the only universally true generalizations to be drawn are trivial or tautological [5].

The paradigm changed to the counterhypothesis after publication of the seminal work of Berlin and Kay [6], whose *universalist view* posits panhuman basic color categories

(BCCs) (► [“Berlin and Kay Theory”](#)). For estimating BCC denotata, the authors employed a standardized array of 330 color stimuli – the “envelope” (Mercator projection) of the Munsell Color Solid, with color chips varying in hue, lightness, and being of highest saturation (see Fig. 1 in ► [“World Color Survey”](#)). In its denotative structure, a BCC is organized around its “best exemplar,” or category *focal color* (see Fig. 4 in ► [“World Color Survey”](#)), and extends to its boundary (► [“Psychological Color Space and Color Terms”](#)). Nonfocal colors in a BCC are characterized by a *graded membership*, as demonstrated by latest empirical and modeling developments [7] (► [“Color Categories and Vagueness”](#)).

According to the universalist view, BCCs recur across languages and are evolving in a partially fixed order, from a minimum of 2 to a maximum of 11 (in industrialized societies) (see Fig. 2 in ► [“World Color Survey”](#); ► [“Berlin and Kay Theory”](#)). Since 1969 the universalist view gathered abundant support from numerous studies around the world that employed the Munsell array and standardized methodology (► [“World Color Survey”](#); ► [“Color Dictionaries and Corpora”](#); ► [“Mesoamerican Color Survey Digital Archive”](#)). Based on new findings, the original model has been revised and elaborated by the authors and their collaborators, with a special regard to sequences of BCT emergence, with the latest version coined *the Universals and Evolution (UE) model* [8].

It is generally agreed that the BCCs emerge and evolve as the result of universal constraints at different levels of color processing [9]. First, the BCC structure is determined by the anatomy and physiology of the human visual system. In addition, it is stipulated by characteristics of color perception per se, articulated by Jameson and D’Andrade [10] as the *optimality hypothesis*: the BCC structure reflects a partition of color space as a way of meaningful information coding of the visible color gamut, so that in the development of the BCT inventory, color categories are added that maximize color differences between adjacent categories and minimize color differences within the new contiguous categories.

Notably, individual language speakers may have their variants of the shared structure – due to physiological differences in the visual system, and/or exposure to different chromatic environments [11], and/or perceptual and cognitive biases that modulate the general constraints (► [“Dynamics of Color Category Formation and Boundaries”](#)).

The universalist view underwent, however, criticisms from proponents of the relativist view. In recent times, based on results of multiple empirical studies, in particular, the WCS, the debate resulted in the compromise of the *weak relativity hypothesis* that reconciles the two extreme theoretical views: it accepts that both category focal colors and boundaries of BCCs may fluctuate between individual languages [12] (see Fig. 5 in ► [“World Color Survey”](#)). The *weak relativity hypothesis* acknowledges that in individual languages, color categories are also shaped by the speakers’ culture-specific, social, and pragmatic factors [2, 4, 9, 13] (► [“Cross-cultural Communication”](#)), as well as by the color diet in the population’s natural environment [14].

Computational simulations that used an extensive number of color stimuli (► [“Color Category Learning in Naming-Game Simulations”](#)) provided decisive evidence that BCCs are not arbitrary: the emergent categorization pattern is dominated by perceptual constraints of human color vision. The language and sociocultural factors are also essential in shaping the color categorization pattern and act against the pressure for uniformity, where population-specific constraints introduce categorical variation stipulated by cultural histories of speaker community.

Modern Age Phenomenon: Increasing Lexical Refinement of Color Categorization

The *weak relativity hypothesis* implies the possibility of new BCCs, which are specific to a certain language. Indeed, recent empirical studies provide accumulated evidence of additional BCCs in some languages, beyond the 11 established by Berlin and Kay [6]. Conceptual and lexical

refinement was recorded, in particular, in the blue area of color space – with “light blue” and “dark blue” BCCs existing in several Slavonic languages (Russian, Ukrainian, Belarusian), circum-Mediterranean languages (Italian, Greek, Turkish, Maltese), some Far East languages (Japanese, Thai), and in Guatemalan and Uruguayan Spanish dialects (for a review see [15]).

Analysis of the emerging BCCs in the languages with more than 11 BCTs prompts that lexical refinement of color space can unfold along one of three ways (for an overview see [15]):

1. Lexical *partition* of the color gamut (assumed in [6]), whereby a novel BCC/BCT emerges as a result of an “old” BCC undergoing fission, or splitting into two, as illustrated by the two blue categories
2. *Insertion* of a new category that straddles the boundaries of existing BCCs, with two color space areas being particularly prone to further lexical differentiation, purple-red and blue-green category boundary
3. *Emergence* of a color category in “under-named” areas of color space that become salient, so a need arises to label them

Furthermore, modern times observe intensive lexical differentiation of BCCs in economically developed cultures – by amplified entrenchment of existing non-BCTs (e.g., “turquoise,” “beige,” “salmon,” “peach,” “magenta,” “cyan,” “fuchsia,” “tan,” etc.) and emergence of new non-BCTs (► [“Color Dictionaries and Corpora”](#)). The general tendency of an increasing refinement of color-space naming is a cognitive response to cultural-economic factors in the globalized world of trade, new technological developments of colored artifacts, and media.

Along with the general factors, lexical refinement of color space is also driven by *language-specific* factors, which reflect cultural influences and visual-environmental statistics, in accord with a hypothesis of usefulness of color to a culture [2, 14, 16] (► [“Cross-cultural Communication”](#)).

Both phenomena were recently analyzed from the viewpoint of general information-theoretic

principles, with the conclusion that the evolution of color-term repertoire is primarily driven by communication constraints [17], with different researchers emphasizing communication pressure [18], communicative need [14], or communication efficiency [16], whereby the differentiated color terminology enables greater chromatic precision of the conveyed color-term denotata. The end-point of categorical and lexical differentiation of color space is, however, unclear.

New Developments in Understanding of Color Category “Basicness”

The challenges to the notion of the 11 BCC/BCT ceiling triggered fresh inquiries into the criteria of the color term “basicness.” Berlin and Kay [6] introduced three main and three auxiliary criteria of “basicness.” Paraphrasing these, to qualify as a BCT, a color name should be:

1. Understood and widely used by all speakers of a language
2. Generalizable across semantic domains and be applicable to any object
3. Psychologically salient
4. Reliably distinguishable from its neighbors in color space

The first two (1, 2) linguistic criteria more recently were scrutinized by Kerttula [19] in her analysis of the British English Corpus: by assessing primacy of color terms (criterion 2), their frequency, number of referents, and derivational productivity and by combining scores for each of these parameters, she arrived at the conclusion of “relative basicness” or a continuum of “basicness” between the most and the least basic color terms. Further, it was found that the ranking matches the order, in which English BCTs have developed historically, whereby a basic color-term status accumulates over time.

The last two criteria (3, 4) are behavioral and emerged more prominently in recent computational studies. Assessment of color term’s psychological saliency (criterion 3) newly underwent conceptual reconsideration: compared to the

broadly accepted conception of psychological saliency as the index derived from the term's order of occurrence and frequency in a color-name listing task (i.e., determined linguistically), alternative notions do not rely on color lexicons. In particular, using WCS color-naming data, Conway et al. [16] cognize psychological saliency of a BCT via the index of its communicative efficiency or surprisal; in comparison, Fider et al. [20] estimate BCT's psychological saliency as the degree of naming consensus by the population members, measured by its "color strength." Finally, criterion (4) is probed in psychophysical studies that employ color stimuli meticulously specified in terms of just noticeable differences (JNDs), to gauge performance at the boundaries of BCCs, in order to capture the influence that language labels exert over the perception and formation of boundaries (e.g., [21] (► "Dynamics of Color Category Formation and Boundaries")).

Visualization of Color Category Concepts

A recent development, driven by empirical studies, computational modeling, and epistemology, is a geometric approach to visualize BCCs, represented as regions of denotata that optimally partition color space (Fig. 1) [22]. The regions of the conceptual color space are "well-formed" (convex), i.e., the colors falling under any BCC

are maximally similar to each other and maximally dissimilar to colors falling under other BCCs (cf. [10]). Such mental representation of color categories results from efficient communication: it reflects an agreement among language speakers in naming colors and is informative and parsimonious, i.e., does not overload memory [22].

Color categories rendered as convex hulls (CIELAB space) enable to represent the structure of individual color spaces and, thus, to capture interindividual differences in color-naming patterns, as well as diatopic variations of color categorization within the same language (e.g., [23]). This line of research opens an avenue for quantifying differences in color categorization patterns between languages, to enable adequate rendition of color-term meanings between these. In addition, it can help apprehending dynamic changes of conceptual color space in ontogenesis and those resulting from bi-/multilingualism.

Concluding Remarks

The field of color categorization currently undergoes further intensive research enquiry – by investigating its universal mechanisms, pattern, structure, and dynamics, determined by perceptual constraints and communication pressure, as well as modulation by culture-specific factors. The ways of research enquiry greatly expanded

Color Categorization: Patterns and Mechanisms of Evolution, Fig. 1 The map of color stimuli densely representing color space (left) partitioned into 11 English basic color categories (right) presented as convex hulls in

CIELUV space. Fig. 4 reprinted from Cognition **193**:104007, Douven, I., Putting prototypes in place. doi: <https://doi.org/10.1016/j.cognition.2019.104007> [22], Elsevier Copyright Clearance Center (2019)

recently: along with continuing empirical studies – of color naming using methods of linguistics and psycholinguistics and gauging color similarity using psychophysical methods – there is a surge of studies that apply elaborate mathematical modeling and computational simulations, all of these providing new insights into the “color concept” mind. Beyond this, color categorization and naming research became the vehicle probing the workings of the mind in general, in particular, the Sapir-Whorf relativity hypothesis of the language effects on perception, and better understanding of the role that sociocultural transmission plays in generating shared linguistic categories among individuals for efficient exchange about the stimuli perceived in the environment

Definition

Color categories are inextricably linked to language as color categories are typically, though not necessarily, associated with color terms. It is believed that the acquisition of categories, including color categories, is influenced by language [1]. Prelinguistic infants do seem to have a set of color categories, which are then either consolidated or modified through observing or engaging in linguistic interactions about color.

Language has been shown to have an influence on a range of modalities, such as time, space, and color. This phenomenon, known as linguistic relativism, shows how the language one uses, and by extension the culture one lives in, has an impact on perception and cognition. It has also been shown that language has an influence on color perception: having a particular color word speeds up spotting a chip of that color among distracting color chips [2, 3]. What is not entirely clear is how language influences the acquisition of color categories. As data on color category acquisition in infants is hard to come by, we can resort to computer simulations to learn more about how language impacts the acquisition of color categories.

A language is a communication system that is shared within a group of language users. As such, a language can be seen as an agreement between all language users on the words and rules of a language, and their meaning. Color words are also subject to this agreement: in the English language speakers agree to use “red” for, among others, the chromatic perception of a ripe tomato, blood, and a light with dominant spectral wavelength of 780 nm. There is no central authority insisting on this: language users themselves agree on this convention. When a new language user, such as a newborn child, enters a linguistic community, it will to varying degrees adopt this convention.

If language is a convention that is agreed upon by a linguistic community, and if language impacts category acquisition, then it follows that categories are to a certain extent also agreed upon by the community. Computer simulations can help us understand how a community can arrive

at an agreement on linguistic conventions and how language shapes concepts and categories.

There are a number of simulation models that can elucidate the process of language acquisition. The Language Game model [4, 5] has proven to be both effective and popular and can be used to study how a group of individuals reach a consensus on linguistic forms and associated categories. If, for example, a new word is introduced in a language, the Language Game model can simulate how that word spreads through the population. The model as such serves to study the dynamics of language change, and by setting parameters of the model, one can study what conditions make a language change. Iterated Learning Models, an alternative model to Language Games, study the sequential transfer of language [6]. Individuals are placed in a chain, and each individual's output is used as input for the next individual. Language Games study horizontal transmission, while Iterated Learning Models study vertical transmission of language. Both models demonstrate how small biases and communication bottlenecks can have a large effect on the language and conceptual structures that arise. A third class of simulated Language Game models are based on Evolutionary Game Theory (e.g., [7, 8]) or Statistical Mechanics (e.g., [9]). These are in essence mathematical models which start from a minimal set of parameters and study the influence of different settings of these parameters.

Language Game Models

In Language Game models, a community of language users is modeled as a population of N software agents. Each agent can store and recall words (or other linguistic information, such as rules) and categories. In the domain of color, the agents store color terms and color categories. In addition, each agent stores associations between color terms and color categories. An association typically is a value showing how strong the association between a term and category is. Agents start with empty inventories and gradually fill these with words and categories.

Various Language Game models represent color in different ways. Color can be modeled as a point on a single circular dimension [7, 8, 10, 11]; a color stimulus is then a real number in the interval $[0, 1]$. For a more realistic model of color, one can endow the artificial agents with a color appearance model, such as the CIE $L^*a^*b^*$ color space [12]. In this space, each color is represented by three real numbers L^* , a^* , and b^* , with L^* representing lightness, a^* the amount of green or magenta, and b^* the amount of yellow and blue. The CIE $L^*a^*b^*$ color appearance model aims to provide an accurate representation of color perception differences and allows for a similarity measure to be calculated between two colors, which is done by taking the Euclidean distance between two color values, permitting a good first approximation to categorical color perception (see [13] for an experimental appraisal and extension of CIE $L^*a^*b^*$).

In addition to the color categories and color terms used by an agent, simulations also need to prescribe what agents do when interacting with each other. In one form of a Language Game model interaction two agents are selected at random from the population; one acts as a *speaker*, the other as a *hearer*. Both agents are presented with a *context*; this is a set of M random color stimuli, each at a distance d from each other. The distance d guarantees that colors are not too similar or identical. From the context one color stimulus is selected, this will be the topic, and the speaker will attempt to communicate what the topic is to the hearer.

The speaker first finds a category that best matches the topic (often, but necessarily, this category is a unique match, meaning that it matches no other stimuli in the context). If no category can be found, the speaker will adapt its category set by adding a new category. Next it finds a word associated with the category and communicates it to the hearer. The hearer will attempt to guess the topic by looking up the word and the associated category in its inventory. It will check which stimulus matches the category best and will “point out” the stimulus. The hearer will then signal if this stimulus is indeed the intended topic. If it is, the game is successful. If the hearer

points out any other stimulus, the game fails. When successful, categories and word-category associations in both agents are reinforced, with the categories used in the interaction adapting such that they match the topic closer. When the game fails, the associations are weakened [4, 5].

During the iterative playing of Language Games [6] the agents create novel categories and words and change existing categories and category-word associations to optimize the communication. Only when communication is good enough (as determined by a preset threshold, e.g., $\tau = 90\%$ of all games end in success) will the agents' internal representations stop changing. It is important to note that the internal representation of all agents at this moment will not be identical and that the agents do not necessarily have the same number of words and categories. Their internal representations are merely sufficiently coordinated for communication to succeed with a success rate of τ . A population typically has a size N between two and several thousand agents and will play tens of thousands or perhaps millions of Language Games before stabilizing. An interesting observation is that the lexical and category systems of the agents adapt until they are "good enough" to successfully communicate; the agents do not need identical words and identical categories; they only need to sufficiently overlap to allow successful communication in most interactions. As such the semantics of words differ between agents: indeed your red is different from my red. As such, word and category are not true descriptions of the world; they are merely useful [14].

The dynamics of Language Game models have been extensively studied, as they inform research into the diachronic evolution of language. For example, the conditions under which a new word or a new linguistic construction is taken up by a language community can be modeled using Language Games [15, 16], and model predictions have been confirmed in studies with human participants [17]. Language Games have been used to clarify the minimum constraints needed to evolve a shared color category system by populations of agents [7], how varying agent perceptual properties impact color category system evolution [18–

20], and how varying color salience affects color category evolution [20]. In the case of color, however, the Language Game model serves a different purpose. It helps us to understand how relatively small biases present in color communications can have large-scale effects on the evolution of color category systems. Small biases are amplified through repeated interactions between language users. Specifically, simulated Language Game models help us formally investigate factors likely to influence color communications and help us understand why color categories appear to be universal and the degree to which pragmatics of communication or culture may contribute to color category evolution.

Explaining the Universal Character of Color Categories

It has been suggested that human color categories exhibit a universal pattern: many cultures have color categories that are seemingly similar. This was first suggested based on tenuous evidence in 1969 by Berlin and Kay [21] and later refined in the World Color Survey [22–24]. As such, color categories are not arbitrary, and this infused a principled search for the basis of their universal character. There are cultures which deviate sufficiently from the universal pattern, virtually ruling out the possibility that color categories are genetically determined. Other processes must be at work, and computer simulations can help us elucidate these.

When agents in a Language Game are communicating about color stimuli, their categories soon converge on a limited set of categories (Fig. 1). The locations in which the categories converge are not predetermined; instead they result from the slight biases introduced by the perceptual system of the agents [12, 18–20, 25]. Two different runs of a simulation will result in two different end results. However, repeated simulations do exhibit a pattern in which some color categories consistently emerge from the interaction between the agents. Categories such as red, green, yellow, blue, white, black, and so forth tend to almost always emerge. This matches the observations in

Color Category Learning in Naming-Game Simulations, Fig. 1 Both plots show all color categories of ten agents plotted in the a^*b^* plane of the CIE $L^*a^*b^*$ color space (the L^* lightness dimension is projected onto the a^*b^* plane; as such *white* and *black* categories are plotted on *top* of each other). The *left* figure shows the state after

500 Naming Games; the categories are still scattered in the color space. The *right* figure shows the state after 15,000 games when the communicate success of the agents is over 85%; the categories have gravitated to a limited number of clusters

the World Color Survey: these basic color terms and categories are found in the majority of the world's languages.

As the repeated playing of Language Games forces agents to coordinate their color categories and color terms, small biases in the agents' color perception will have a large influence. Belpaeme, Bleys and Steels [12, 23] showed how the bias of the CIE $L^*a^*b^*$ color appearance model together with a repeated negotiation of linguistic conventions results in the emergence of universal patterns of color categories. Baronchelli et al. [11] refined this; again using a Language Game model they showed how the human Just Noticeable Difference (JND) function, a function which shows the wavelength differences that are just about distinguishable to the human eye for each wavelength in the visual spectrum, also provides a small but important bias that can explain the universal character of color categories.

Language Games show how a variety of factors may contribute to the universal character of color categories without the need for color categories to be explicitly genetically determined. They permit the evaluation of, for example, neurophysical properties of human color perception as well as other small biases which, through

repeated linguistic negotiations, amplify and can contribute to the similarities seen across groups of languages that have roughly similar color categories.

Color Centers

Richard J. D. Tilley
Queen's Buildings, Cardiff University,
Cardiff, UK

Definition

Color centers are point defects or point defect clusters associated with trapped electrons or holes in normally transparent materials. These centers cause the solid to become colored when the electronic ground state of the defect is excited to higher energy states by the absorption of visible light [1–5]. [Note that transition metal and lanthanoid ion dopants that engender color in an otherwise colorless matrix are frequently called color centers. These are dealt with elsewhere (see “[Cross-References](#)”).]

Color Centers

The concept of color arising from point defects was initially developed in the first half of the twentieth century, principally by Pohl, in Germany. It was discovered that clear alkali halide crystals could be made intensely colored by diverse methods, including irradiation by X-rays, heating crystals in the vapor of any alkali metal, and electrolysis. Crystals with induced color were found to have a lower density than the crystals before treatment and appeared to contain a population of anion vacancies. The absorption spectrum was always a simple bell shape. It was notable that the color engendered in the crystal was always the same and was not dependent upon the method of color production. That is, if a crystal of KCl was heated in an atmosphere of any alkali metal, or irradiated by X-rays, or electrolyzed using any cathode material, the crystal took on a violet color. Similarly, crystals of NaCl always took on an orange brown hue under all preparation methods. The fact that the color was a unique property of the host structure implied that it was a property of the crystal itself. The color was

ultimately attributed to the formation of defects called *Farbzentren* (= color centers), which were equated with mistakes in the crystal structure.

Since these early studies, many different color center types have been characterized (Table 1). All are electronic defects that possess similar characteristics in that they form in colorless, insulating, often relatively ionic, solids and incorporate either trapped electrons, to produce *electron excess centers*, or trapped holes, to produce *hole excess centers*. Solids may contain several different types of color center, including populations of both electron and hole excess centers in the same host matrix. Color centers are usually labelled with a letter symbol (Table 1).

As the alkali halide studies demonstrated, color centers can be created in a host matrix in a number of ways. For example, strong ultraviolet light can transform clear glass into purple-colored “desert glass” and intense radiation from nuclear weapons or accidents may color ceramics such as porcelain a blue color, both changes being due to the formation of color centers. Controlled irradiation in nuclear reactors or similar is used to produce artificial gemstones from colorless and less

valuable starting materials. For example, irradiation of colorless topaz, $\text{Al}_2\text{SiO}_4(\text{F}, \text{OH})_2$, induces a beautiful blue color due to color center formation (Fig. 1).

From an optical viewpoint, color centers behave something like isolated atoms dispersed throughout the host matrix. As such, they make ideal probes of the interaction of light with the matrix and are currently being explored for wide ranging electro-optic applications.

F Centers: Electron Excess Centers

The first color center to be characterized was the F center found in alkali halides, and these remain the best-known electron excess centers. Anion vacancies, which occur in low concentrations in alkali halides, MX , have an effective positive charge and an F center is an anion vacancy (V_X) plus a trapped electron to form an effectively neutral defect ($\text{V}_\text{X} \text{e}$) (Fig. 2a). The F center behaves rather like an isolated hydrogen atom in the structure, and the electron is able to absorb electromagnetic radiation, jumping from one energy level to another, just as an electron absorbs radiation in the Bohr model of the H atom. The

Color Centers, Table 1 Some color centers

Host crystal	Symbol	Description
Alkali halide: MX	F	Electron trapped an anion vacancy
	M, F_2	A pair of adjacent interacting F centers
	F_A	F center next to an alkaline metal substitutional impurity
	F', F^-	F center with two trapped electrons
	$\text{R}, \text{M}^+, \text{F}_2^+$	Three adjacent interacting F centers on (111)
	V_K	Two adjacent anion vacancies with one trapped electron
Alkaline earth halide: MX_2	F	Electron trapped an anion vacancy
	M	A pair of adjacent F centers aligned along [100]
	F_3	Three adjacent F centers aligned along [100]
Alkaline earth oxide: MO	F	Oxygen vacancy with two trapped electrons
	F', F^-	Oxygen vacancy with three trapped electrons
	F^+	Oxygen vacancy with one trapped electron
Quartz: SiO_2	E', E^-	Oxygen vacancy with one trapped electron
Diamond: C	C, P1	Isolated N atom substituted for a C atom
	A	Two C atoms substituted by N, forming an N-N pair
	N3	Three N atoms on C sites surrounding a C vacancy
	N2	Two N atoms on C sites adjacent to a C vacancy
	NV	One N atom on a carbon site adjacent to a C vacancy
	NV^-	Negatively charged NV center

peak of the absorption curve, $\lambda_{\max}$, corresponds to a total removal of the electron from the F center, and usually falls in the visible, so coloring the originally transparent crystals (Table 2). In terms of band theory, alkali halides are insulators with a considerable energy gap between a filled valence band and an empty conduction band. The F center in its ground state creates a new energy level or narrow energy band in the band gap (Fig. 2b). The

Color Centers, Fig. 1 Blue topaz, produced by irradiation of clear crystals; the color arises from a population of color centers. (Photograph R J D Tilley)

color-producing optical absorption peak corresponds to electron promotion into the conduction band. The variation in the color observed depends upon the host crystal band gap and the energy level of the F center, both of which are linked to the lattice parameter of the host matrix (Table 2).

The detailed mechanism for the formation of F centers depends to some extent upon the manner in which they are generated. In the case of irradiation by X-rays, for example, the energetic radiation is able to displace an electron from a normal anion, and some of these become trapped at existing anion vacancies. The corresponding anion that has lost an electron creates a hole energy level in the valence band.

F centers occur in many alkaline earth halides and oxides (Table 1). For example, the mineral *Blue John* is a rare naturally occurring purple blue form of fluorite, CaF_2 . The coloration is caused by F centers believed to have formed when the fluorite crystals were fortuitously located near to uranium compounds in the rock strata. Radioactive decay of the uranium produced the energetic radiation necessary to form the color centers.

Hole Excess Centers

One of the best understood hole excess centers gives rise to the color in smoky quartz, a naturally occurring form of silica (SiO_2). This material

Color Centers, Table 2 Alkali metal halide F centers

Compound	Absorption peak $\lambda_{\text{max}}/\text{nm}$	Color ^a	Lattice parameter/nm
LiF	235, ultraviolet	Colorless	0.4073
NaF	345, ultraviolet	Colorless	0.4620
KF	460, blue	Yellow brown	0.5347
RbF	510, green	Magenta	0.5640
LiCl	390, ultraviolet (just)	Yellow green	0.5130
NaCl	460, blue	Yellow brown	0.5641
KCl	565, green	Violet	0.6293
RbCl	620, orange	Blue green	0.6581
LiBr	460, blue	Yellow brown	0.5501
NaBr	540, green	Purple	0.5973
KBr	620, orange	Blue green	0.6600
RbBr	690, red	Blue green	0.6854

^aThe appearance of the crystal is the complementary color to that removed by the absorption band

contains small amounts of Al^{3+} substitutional impurities. These replace Si^{4+} ions in $[\text{SiO}_4]$ tetrahedral units which form the building units of the crystal. Overall charge neutrality is preserved by the incorporation of one H^+ for each Al^{3+} . These H^+ ions sit in interstitial positions in the rather open SiO_2 structure. The color center giving rise to the smoky color in quartz is formed when an electron is liberated from an $[\text{AlO}_4]$ unit by ionizing radiation and is trapped on one of the H^+ ions present, leaving a hole (h) behind. The color center is a $(\text{AlO}_4 \text{ h})$ group. The color arises when the trapped hole absorbs radiation exactly as the electron in an F center.

The situation in amethyst, which is a form of silica containing Fe^{3+} and H^+ impurities, is similar. The impurity Fe^{3+} forms $[\text{FeO}_4]$ groups. These crystals are known as the pale yellow semiprecious gemstone citrine and also in a pale green form; the color arising from the impurity Fe^{3+} ions (see “[Cross-References](#)”). On irradiation, $(\text{FeO}_4 \text{ h})$ color centers form by interaction with H^+ ions. The color centers impart the purple amethyst coloration to the crystals (Fig. 3).

Color Centers in Diamond

Colored Diamonds

The diamond structure is built up of carbon atoms each coordinated to four carbon atom neighbors;

Color Centers, Fig. 3 Amethyst crystals; the purple color arises from a population of color centers. The pale green stone is unirradiated. (Photograph R J D Tilley)

the linking being via tetrahedral sp^3 hybrid bonds (Fig. 4a). Diamond has a band gap of about 5.5 eV which is too large to absorb visible light and perfect diamonds are clear. The commonest impurity in natural diamonds is nitrogen, which mostly substitutes for carbon on normal tetrahedral sites in the crystal. Natural diamonds are often subjected to temperatures of 1000–1200 °C, over geological timescales, allowing these nitrogen atoms to diffuse through the structure, leading to

populations of defect clusters as well as isolated point defects.

The color of the highly prized natural yellow diamonds called *Canaries* is due to isolated nitrogen atoms located on carbon sites, which form color centers called C centers. The color arises in the following way. Nitrogen, with an electron configuration $1s^2 2s^2 2p^3$, has five bonding electrons, one more than carbon, with a configuration $1s^2 2s^2 2p^2$. Four of the electrons around each impurity nitrogen atom are used to fulfill the local sp^3 bonding requirements of the crystal structure and one electron remains unused. Substitution of nitrogen for carbon on a normal carbon atom site in the crystal thus creates an electron excess color center (Fig. 4b). On an energy level diagram, this gives rise to a donor level in the band gap, which, because of lattice vibrations and other interactions, consists of a narrow band of energies centered at 2.2 eV and extending to 1.7 eV, the ionization energy of the N atom in diamond. The electron can be excited into the conduction band by absorption of incident visible light of wavelengths longer than about 564 nm, giving the

stones a faint yellow aspect. As the number of C centers increases, the color intensifies.

The N3 center, which consists of three nitrogen atoms on neighboring carbon sites adjacent to a carbon vacancy, seems to be responsible (at least in part) for the pale straw color of expensive *Cape Yellow* diamonds. The N3 center has a complex electronic structure which absorbs just in the blue end of the visible, at 415 nm, resulting in yellowish stones. The N3 centers are often accompanied by neutral N2 centers consisting of two nitrogen atoms on neighboring carbon sites adjacent to a carbon vacancy. These absorb at approximately 475 nm, giving a yellow color to the stones and adding to that contributed by the N3 clusters. When crystals are irradiated, either naturally or artificially, the N2 cluster can trap an electron to form a negatively charged $N2^-$ center that has an absorption peak at approximately 989 nm in the infrared. This absorption band can spill over into the red part of the visible spectrum, leading to stones with a blue tone and producing blue diamonds. When all these nitrogen-based color

C

Color Centers, Fig. 4

(a) The diamond structure as a linkage of tetrahedrally coordinated carbon atoms (*small circles*); (b) structure of a C center in diamond consisting of a nitrogen atom (*large circle*) occupying a carbon position, schematic; (c) structure of a boron impurity center (*large circle*) in diamond (schematic)

centers are present in roughly equal quantities, the stones take on a green hue.

Although nitrogen-linked color centers give rise to the highly valued yellow hued diamonds, many prized blue diamonds are the result of boron impurities on normally occupied carbon atom sites (Fig. 4c). Boron, with an electron configuration $1s^2 2s^2 2p^1$, has only three outer bonding electrons instead of the four found on carbon. These three are used in fulfilling the bonding requirements of the structure, but one bond of the four is incomplete and lacks an electron, making the defect a hole excess center. In semiconductor physics terms, the center introduces a narrow band of energy levels approximately 0.4 eV above the valence band. The transition of an electron from the valence band to this band gives rise to an absorption peak in the infrared with a high-energy tail encroaching into the red at 700 nm. The boron-doped diamonds therefore absorb some red light and leave the gemstone with an overall blue color.

Nitrogen-Vacancy Centers

The diamond color center that has been studied in most detail is that consisting of a single nitrogen substitutional impurity located next to a carbon vacancy, together with a trapped electron to form a *negatively charged nitrogen–vacancy center*, NV^- (often just called an NV center). These defect centers are readily created by the irradiation of nitrogen containing natural or synthetic diamonds, diamond thin films or diamond

nanoparticles with high energy protons. The proton irradiation results in the formation of carbon vacancies, and if the crystals are then annealed at above 600 °C, the temperature at which the vacancies become mobile, they diffuse through the structure until they encounter a nitrogen impurity. The strain around the nitrogen atom effectively traps the vacancy, preventing further migration. In the resultant NV^- centers, the tetrahedron surrounding the carbon vacancy is composed of three carbon atoms and one nitrogen atom (Fig. 5a).

These centers are being investigated for applications, including room temperature quantum computing, nanoscale magnetometers, fluorescent markers, and biological imaging [6, 7]. The applications follow from the unique features of the energy levels of the (NV^-) center. The ground state term of the electronic structure is 3A and the first excited state term is 3E (Fig. 5b) [see “Cross-References”: Transition-Metal Ion Colors, for a description of 3A and 3E terminology.] (Note that both the ground state and excited state terms are split into several levels. This splitting is of prime importance for many applications but does not dominate the overall color aspects of the centers and can be ignored in the present context.) Excitation from the 3A ground state to the 3E excited state is by absorption of light over the range of approximately 514–560 nm, giving stones a pink hue. Emission falls in the range 630–800 nm, but the observed color is dominated by a particularly strong red fluorescence at

Color Centers, Fig. 5 (a) An NV^- center in diamond, schematic; (b) approximate energy level diagram of an NV^- center

637 nm. Under suitable observing conditions, single bright red fluorescent (NV^-) centers can be observed, making nanodiamonds that incorporate these defects ideal probes to track vital processes in living cells [7].

Tenebrescence

Tenebrescence (reversible photochromism) is the property of darkening, especially reversibly, in response to incident radiation. It is associated particularly with minerals which change color when exposed to sunlight. The color fades when the sunlight is shaded, and the effect can be repeated indefinitely. The best known minerals which exhibit tenebrescence are scapolite $(\text{Na,Ca})_4(\text{Al,Si})_3\text{Si}_6\text{O}_{24}(\text{Cl,CO}_3, \text{SO}_4)$; tugtupite, $\text{Na}_4\text{AlBeSi}_4\text{O}_{12}\text{Cl}$; and hackmanite, $\text{Na}_8\text{Al}_6\text{Si}_6\text{O}_{24}(\text{Cl,S})_2$, also given the formula $(\text{Na}_8(\text{Al,SiO}_4)_6(\text{Cl,S})_2$, reflecting that variable Al to Si concentrations may be present

Hackmanite is a derivative form of sodalite, $\text{Na}_8\text{Al}_6\text{Si}_6\text{O}_{24}\text{Cl}_2$, in which some of the Cl has been replaced by a sulfur containing group S_2^{2-} , SO_3^{2-} , or SO_4^{2-} . The tenebrescent colors observed in originally colorless hackmanite crystals range over pink, red, purple, and blue. These colors appear rapidly when the crystals are exposed to strong sunlight or ultraviolet light and then fade over the course of several minutes when in shadow. This coloring and fading process can be repeated indefinitely. For tenebrescence to occur it is found that only a low level of S is required, amounting to just a few percent. At greater concentrations, the effect is lost.

The structure of hackmanite is cubic and is built of rings of four apex-linked SiO_4 and AlO_4 tetrahedra centered on each cube face and rings of six similar apex-linked tetrahedra around each cell corner. These form cubo-octahedral cavities containing the Na^+ cations and the Cl^- anions. In order to maintain charge balance in the tenebrescent crystals, the interpolation of, for example, an S_2^{2-} anion into a cavity requires the loss of 2Cl^- anions, which thereby introduces an anion vacancy into a nearby cavity where it is associated with surrounding Na^+ cations in a

$(\text{Na}_4\text{V})^{4+}$ cluster. Although the mechanism for the tenebrescence has not been fully elucidated, it is believed that an electron is released from S_2^{2-} groups by ultraviolet irradiation and this migrates to the nearby $(\text{Na}_4\text{V})^{4+}$ cluster where it becomes trapped. This trapping center acts as a color center and so colors the normally clear crystals. The color observed is proportional to the lattice parameter of the hackmanite, which itself is a reflection of the size of the F center. The trap energy is quite low, however, and the electrons are liberated by thermal energy and diffuse back to the sulfur groups, where they are again incorporated. This leads to the diminishing color after the exciting radiation is removed.

Some Applications of Color Centers

F Center Lasers

F centers do not exhibit laser action but F centers that have a dopant cation next to the anion vacancy are used in this way. These are typified by F_{Li} centers, which consist of an F center with a lithium ion neighbor. Crystals of KCl or RbCl doped with LiCl, containing F_{Li} centers, have been found to be good laser materials, yielding emission lines with wavelengths between 2.45 and 3.45 μm . A unique property of these crystals is that in the excited state an anion adjacent to the F_{Li} center moves into an interstitial position. This is *type II* laser behavior, and the active centers are called F_{Li} (II) centers. These centers are stable if the crystal is kept at -10°C .

Persistent Luminescence

Color centers are active in materials that show persistent luminescence. In these compounds, irradiation by ultraviolet light present in normal daylight gives rise to luminescence for many hours after dark. Such materials are making their way into applications as diverse as road signs that do not need a power supply at night and bicycle frames that glow in the dark.

Although the color centers responsible for persistent luminescence vary from material to material, the principle can be illustrated with the oxide SrAl_2O_4 doped with B^{3+} , Eu^{2+} , and Dy^{3+} , which

gives a green luminescence. The SrAl_2O_4 structure consists of a framework of corner-linked $[\text{AlO}_4]$ tetrahedra enclosing Sr^{2+} ions in the cavities so formed. The B^{3+} substitutes for Al^{3+} to create $[\text{BO}_4]$ tetrahedra and $[\text{BO}_3]$ triangular groups, which can be thought of as $[\text{BO}_4]$ tetrahedra in which one of the oxygen ions is absent to form an oxygen vacancy (V_O), creating a $(\text{BO}_3 \text{V}_\text{O})$ center. The substitution of Dy^{3+} for Sr^{2+} results in a charge imbalance that is compensated for by the creation of an equal number of vacancies on Sr^{2+} positions (V_Sr) to form defect clusters ($\text{Dy BO}_4 \text{V}_\text{Sr}$). Following irradiation with ultraviolet light, an electron is transferred from a $(\text{BO}_3 \text{V}_\text{O})$ cluster to a $(\text{Dy BO}_4 \text{V}_\text{Sr})$ unit, resulting in the formation of two complex color centers: $(\text{Dy BO}_4 \text{V}_\text{Sr} \text{h})$ which are hole excess centers and $(\text{BO}_3 \text{V}_\text{O} \text{e})$, which are electron excess centers. The origin of the luminescence lies in this pair of color centers. Under normal conditions, the electron and hole centers are metastable, and over the course of several hours, the holes and electrons gradually recombine. The energy liberated is transferred to the Eu^{2+} ions, which lose energy by the emission of photons, thus producing a long-lasting green fluorescence.

Photostimulable Phosphors

Photostimulable phosphors that make use of color centers are widely used in X-ray imaging, particularly by dentists, where they have largely replaced X-ray film recording. The first commercial material to fulfill these requirements, introduced in 1983, was BaFBr doped with Eu^{2+} . Although the detailed mechanism by which these phosphors work is still not entirely clear, it is established that an important component of the process is the formation of F centers, produced as a result of the X-ray irradiation. In dental X-ray imaging, a plate covered with a thin layer of phosphor is placed into the mouth and exposed to X-rays. The X-rays initially displace an electron from an anion to form an electron–hole pair. The electron is subsequently trapped at an anion vacancy to form an F center. This fairly stable pair of electronic defects constitutes a *latent image* in the phosphor. Subsequently, the exposed plate is irradiated with 633 nm light from a helium–neon

laser. The electrons trapped in the F centers are initially promoted to the conduction band, after which they are free to recombine with the holes. The energy liberated is transferred to Eu^{2+} ions which decay from the subsequent excited state by the emission of visible light at 420 nm, subsequently recorded as a digital image. The number of F centers and holes, and therefore the amount of light emission, is proportional to the X-ray intensity in the phosphor. The optical image thus records accurately the degree to which the X-rays have penetrated the subject.

Postscript

The electronic structures of the neutral NV and negative NV^- color centers in diamond have been intensively studied, and it has taken some 35 years to reach the current understanding of energy levels of this defect. It would seem reasonable to suspect that similar detailed investigations of the other color centers described will also lead to significant revisions in their electronic structures and consequently a more precise description of their color-engendering abilities.

[Color wheel](#); [Hue sequence](#)

Definition

The color circle, as generally understood and widely used, is a diagram with a continuous sequence of hues arranged in the order of the spectrum. (The gap between spectral red and spectral violet is bridged with extra-spectral purples.) The color circle diagram is used as a guide to mixing and color composition. It is also used in the classification of colors and is incorporated in all three-dimensional color order systems.

Introduction

Very many color circle diagrams have been designed and published. The essential feature is that the diagram must represent the sequence of hues in correct order and in a continuum: reds, oranges, yellows, greens, blues, purples, reds, oranges, yellows, greens, etc. The number of separate hues in the sequence can vary as can the hues themselves that are selected for inclusion. The starting point for some color circles is a choice of so-called primary colors. Other circles are organized so that colors opposite to each other are, in

some sense, complementary. Many color circles are also organized so that the degree of difference between neighboring colors in the sequence appears to be the same all round the circle.

The Variety of Color Circles

There is no single “correct” design for a color circle. Different circles have been constructed on different principles. They are not necessarily presented in color; in some the colors are simply identified by name. Color circles can be grouped in three broad categories: those that represent colors as something physical, those that represent colors as visual phenomena – what people see –, and those where the colors can be understood as either or both, physical and/or visual. In the first category the colors represent lights, paints, inks, or dyes, and the position of the colors in relationship to each other is generally determined by their physical properties or by the way that these lights, paints, inks, or dyes can be mixed to produce a large range of other colors. In the second category the colors are simply themselves and it is their appearance that determines how they are related in the circle. In the third category it may not be clear whether the colors are to be understood as physical or visual or both. It could be that the designers and users of such circles confuse or conflate the physical and the visual aspects of color. For an account of the way that the physical and visual aspects of color can be confused or conflated, see the entry on ► [“Primary Colors”](#) in this encyclopedia.

As color circles fall into different categories, and are constructed according to different principles, the relationship between colors can vary from circle to circle. This does not mean that the sequence of hues can vary – that must always be the same – but the distance between hues can vary. For example, it could be that two different circles have yellow in the 12:00 o’clock position, but red might be at 3:00 o’clock in one circle and at 4:00 o’clock in the other. The principles underlying the design of the color circles would have fixed the position of red in relation to yellow. Problems can arise when there is a mismatch between the intentions of the designer and the expectations of the

user. A particular color circle can be criticized for not representing particular color relationships when it was never the intention that such relationships be embodied in the design.

Precursors to the Color Circle

The color circle, as defined above, was invented by Isaac Newton, whose color circle is illustrated in his book *Opticks*, first published in 1704 (see Fig. 4) [1, pp. 32–35]. Before Newton it was believed that there was a beginning and an end to the sequence of colors. Aristotle had claimed that all colors derived from mixtures of white and black which he placed at either end of a linear scale [2, pp. 31–32]. Aristotle's prestige was so great that science was dominated by his ideas until the time of Galileo [3, p. 213]. Some circular color diagrams do predate Newton but they still reflect Aristotle's ideas.

John Gage describes a circular diagram that survives in an illuminated manuscript from the fifteenth century. This shows the colors of urine, between white and black, that helped physicians diagnose certain diseases [4, pp. 162 and 171]. White and black also appear in other circular diagrams, two in a manuscript by Sigfrid Forsius (1611) and another in a printed medical text by Robert Fludd (1629–1631). Fludd's circle has this sequence: white, yellow, orange, red, green, blue, and black [2, p. 42]. Forsius echoes Aristotle

when he writes: “Among colours there are two principles, white and black, from which all others arise” [5, pp. 12–13]. The Forsius manuscript contains two circular diagrams. Each has white in the 12:00 o'clock position and black at 6:00 o'clock. Forsius explains that his first circle illustrates the way in which the “Ancients” arranged the colors. Down the left side, between white and black, are pale yellow, yellow, orange, red, purple, brown, and violet. Down the right side are ash gray, gray, sky blue, blue, pale green, green, and dark green. The second Forsius diagram is shown in Fig. 1 and recreated in Fig. 2 with color names translated from old Swedish.

Claims have been made that this second Forsius diagram represents a sphere [7, p. 224]. If this is correct then the central horizontal line must be read as a circle seen from the side with red, yellow, green, and blue on the circumference and gray in the middle. Werner Spillmann has applied the principles of graphic projection to this interpretation and points out that it would mean that the hues are in the wrong order [8, p. 7]. Yellow must be closest to the observer and green farthest away or vice versa. Either way, the hue sequence would be red, yellow, blue, and green, which is not the order in which they appear in the spectrum. However these early diagrams are read, not one of them, unequivocally, shows the sequence of hues as continuous and in the correct order.

Fig. 2 Reconstruction of the Forsius diagram with color names translated from old Swedish

Development of the Color Circle

The color circle did not evolve so much as to develop a growing variety of uses. Newton’s circle identifies colors with light of different wavelengths and he shows how the diagram can be used to illustrate the results of additive mixing. Some later circles illustrate the results of subtractive mixing from a set of “primaries.” In other circles the positions of the colors are determined by how they appear. Such arrangements are used in systems of color identification. Color circles have been developed where the apparent difference between neighboring colors is the same all round the circle. Colors that are opposite to each other in some circles are described as being complementary. Even spacing and complementary relationships are seen as significant in theories of color harmony.

Newton

In Fig. 3 Lindsay MacDonald is showing how white light is refracted by a prism to reveal the different colors. Although not easily visible here, the blue shades into a slightly reddish violet at the short-wave end of the spectrum. Perhaps it was

Color Circle, Fig. 3 Lindsay MacDonald demonstrating how a prism separates white light into different colors

the redness at each end of the spectrum that gave Newton the idea of connecting the two ends to form his circle. Newton’s color circle is shown in Fig. 4.

Strictly speaking, the sequence of hues in Newton’s circle is incomplete. The circle is divided into seven segments, each identified by name. At first Newton refers to each segment as representing a single color – “Let the first part

Color Circle, Fig. 4 Isaac Newton's color circle representing colors as different wavelengths of light. (Reproduced from Ref. [6], with permission)

DE represent a red, the second EF orange . . .” – but he goes on to say that these represent “all the colors of uncompounded light gradually passing into one another as they do when made by Prisms . . .” [1, p. 32]. So the segment DE does not represent a single red but a range of the hues that would be identified as “red.” And the lines that separate the segments represent the borders where colors that would be identified by one name give way to those that would be identified by the next; the “red” segment would have a range of colors from reds to orange-reds. Because the colors in the circle represent the wavelengths of light in the visible spectrum, there is no place for the bluish reds and purples that are not visible in the spectrum. And if the hues shade into each other across the borders separating the other named segments, there would be a break in the sequence at point D with no spectral hues to shade from violets to reds.

A color circle which does show all the hues, spectral and non-spectral, shading into each other was produced by Michel-Eugène Chevreul and published in 1864 (Fig. 5). This can be set beside another of Chevreul's circles (Fig. 6) which is divided into 72 hues. Chevreul's color circles are described by Verena Schindler [9, pp. 66–68].

The colors in Chevreul's circle between the 5:00 o'clock and 7:00 o'clock positions are not visible in the spectrum and so have no place in Newton's circle. However, if Newton had intended to represent seven hues only, with no shading from one named hue to the next, the gap between violet and red would be no more noticeable than that between red and orange. The hues are in the correct order and the sequence is continuous.

The First Color Circles Published in Color

The first color circles to be published in color appear in an enlarged edition of a book on miniature painting. The author of the first edition of 1673 has been identified as Claude Boutet, but the color circles were only added in the enlarged edition of 1708 in a new section on pastel painting. The unknown author of this later section writes: “Here are two circles by which one will be able to see how the primitive colors, yellow, fire red, crimson red and blue generate the other colors” [2, p. 57]. So these circles are demonstrations of subtractive mixing with paints (Fig. 7). The possibility of mixing a complete sequence of

hues from just three “primitive colors” was already known at that time so the use of two “primitive” reds is striking. Perhaps the author did not think that any available red pigment could qualify as “true red” so two reds had to be

used, one a yellowish red and the other bluish. And perhaps no single red could deliver a satisfactory orange as well as a satisfactory purple. In this respect these early color circles foreshadow the Color Bias Wheel devised by Michael Wilcox

Color Circle, Fig. 7 Color circles from the enlarged 1708 edition of the *Treatise on Miniature Painting*. (Reproduced from Ref. [6], with permission)

[10, p. 15]. To make sure that an artist can achieve vivid colors all round the circle, Wilcox has two blues and two yellows as well as two reds in his Color Bias Wheel.

Harris

Moses Harris held to the belief that “all the variety of colours . . . can be formed from Red, Blue, and Yellow” [11, p. 3], but he seems to have recognized the shortcomings of available pigments. He explains that he “treats on colour in the abstract” [11, p. 7]. This suggests that he had in mind some kind of theoretical ideal. As he points out, “Colour which we may call material, or artificial, are very imperfect in themselves, and being made of

various substances . . . maketh the colouring part extremely difficult . . .” [11, p. 7]. For Harris, red, blue, and yellow were “primitives” which could be mixed to produce the “mediates” purple, green, and orange. He does list representative pigments: vermilion, ultramarine, and king’s yellow for the “primitives” and sap green and red orpiment for two of the “mediates” (no pigment is listed for purple). The fact that he lists separate pigments for his “mediates” suggests that these pigments would have been used, in addition to vermilion, ultramarine, and king’s yellow, to paint the color circles in his book – this is to make his demonstration of the theory more convincing with acceptably vivid colors all round the circle (Fig. 8).

Color Circle, Fig. 8 Color circle by Moses Harris 1772. (Reproduced from Ref. [6], with permission)

Harris was an entomologist as well as an accomplished artist. Reference to his color circles would have been helpful when identifying and recording the colors of butterflies and other insects, while the circles could also serve as a guide to mixing paints to match those colors. Furthermore, Harris may have been the first to point out that a color circle can reveal relationships between colors that would now be called complementary. He refers to “contrasting colors” that are “so frequently necessary in painting” [11, p. 6] and goes on to explain how one should “look for the colour . . . in the system, and directly opposite to it you will find the contrast wanted” [11, p. 6]. And he provides a kind of definition: “if the colours so mixed are possest of all their powers, they then compose a deep black” [11, p. 7]. One current definition of complementary colors is that they should mix to a neutral – white from additive mixture in the case of lights, gray from partitive mixing in the case of colored segments on a spinning disc, and near black from subtractive mixing in the case of paints. At the end of the book, Harris

describes the phenomenon of colored shadows. He explains that a stick placed in the orange light of a candle will cast a blue shadow, this result being predictable from the positions of orange and blue on opposite sides of his circle. A more extensive discussion of complementary colors can be found under that heading in this encyclopedia.

Goethe

Johann Wolfgang von Goethe is best known as a writer of novels, plays, and poetry, but he also wrote a book on color theory which remains influential today. Goethe was satisfied that “yellow, blue, and red, may be assumed as pure elementary colours, already existing; from these, violet, orange, and green, are the simplest combined results” [12, p. 224]. When these six colors are arranged in a circle, yellow is opposite violet, blue is opposite orange, and red is opposite green. Goethe places great emphasis on such relationships: “the colours diametrically opposed to each

other in this diagram are those which reciprocally evoke each other in the eye” [12, p. 21]. This can be recognized in afterimages and Goethe describes his experience of a “beautiful sea-green” when a girl wearing a scarlet bodice moved out of sight [12, p. 22]. He argues that such experiences show how the eye demands completeness. The red bodice gave way to green as a union of blue and yellow. Goethe saw in afterimages “a natural phenomenon immediately applicable to aesthetic purposes” [12, p. 320]. The afterimage phenomenon provides another way of defining complementary relationships with the added claim by Goethe that such relationships are beautiful. So Goethe is reinforcing the notion that the color circle can be seen as a tool for developing harmonious color combinations.

Chevreul

Michel-Eugène Chevreul developed a set of nine color circles, graded from full hue (Fig. 6) to almost black, and each with 72 hues, as the basis of a comprehensive color order system. In his introduction to a translation of Chevreul’s book *De la loi du contraste simultané des couleurs*, Faber Birren explains how “Chevreul devoted himself not only to color organization, color harmony, and contrast effects, but to methods of naming and designation of colors” [13, p. 29]. A special memorial edition of Chevreul’s book was published by the National Press of France in 1889 when Chevreul himself was 103 years old. The potential confusion between the physical and visual aspects of color is evident in a prefatory note to this edition: “In order to guarantee to the plates of this book the stability which their scientific nature requires . . . it was necessary to resort only to mineral colors whose stability was certain. . . . Since the three colors chosen by Chevreul as basic, *red, yellow, blue*, cannot be reproduced precisely by means of isolated materials, they were obtained by mixing” [13, p. 27]. If the “basic” colors red, yellow, and blue could only be obtained by mixing, their status as “basic” would need to be clarified.

Hering

The primacy of red, yellow, and blue was challenged by Ewald Hering. The scientific orthodoxy that emerged during the nineteenth century was that three primary colors had their counterparts in the human eye in the form of three different types of receptor cell, each tuned to one of these primaries. This notion was first proposed by George Palmer when he suggested that “the surface of the retina is compounded of particles of three different kinds, analogous to the three rays of light” [14, p. 41]. Thomas Young, working independently, came to a similar conclusion. Young suggested that the sensitive particles in the retina were associated with “the three principal colours, red, yellow, and blue” [15, p. 147]. In a subsequent lecture he referred to “three simple sensations . . . red, green and violet” [16, p. 440]. Hering could not reconcile any set of three primary colors with his own subjective experience. For Hering there are six basic color phenomena – six *urfarben* – white, black, yellow, red, blue, and green. Since it is possible to describe the hue of any color in relation to yellow, red, blue, and green, Hering proposed that “corresponding to the four hue variables . . . there are four physiological variables” [17, p. 48]. Hering, therefore, designed a color circle which represented colors simply as visual phenomena with yellow, red, blue, and green as primaries (Fig. 9).

The Natural Color System (NCS)

Hering’s theories were developed in Sweden and are the basis for the Natural Color System (NCS) (Fig. 10). As with Hering’s color circle, the NCS has four “elementary colors” which are defined in visual terms as a yellow that is neither greenish nor reddish, a red that is neither yellowish nor bluish, a blue that is neither reddish nor greenish, and a green that is neither bluish nor yellowish [18, p. 132]. It is important to note that the NCS was designed just as a means of describing colors and showing how they are related as visual phenomena. The NCS is “value neutral in that it does not give rules for what is ugly and what is

Color Circle, Fig. 9 Color circles by Ewald Hering. (Reproduced from Ref. [6], with permission)

attractive” [19, p. 4]. There are no claims that it is to be used as a guide to color harmony. It has been criticized for not having the degree of difference between neighboring colors the same all round the circle. Although the colors are shown in a continuous circle, the four elementary colors are to be understood as the beginnings and ends of four separate hue sequences. The colors between red and blue are equally spaced visually as are the colors between blue and green, but there is a greater degree of visual difference in the red to blue sequence than in the blue to green.

Ostwald

Wilhelm Ostwald developed a color circle that is superficially similar to that of Hering and the NCS in that it is based on four rather than three “fundamental colors” (Fig. 11). However, these colors are not treated as the beginning and end points of four separate hue sequences but simply as landmarks in one continuous sequence. For Ostwald, the color opposite to a given color should be the one that is “most different” so that “the entire circle is filled with such pairs of contrasting

Color Circle, Fig. 10 Color circle of the Natural Color System (NCS). (Reproduced from Ref. [6], with permission)

colors, which shall be called complementary colors” [20, p. 34]. The complementary relationship is established by optical mixture using a spinning disc. Segments of yellow and red on a disc would blend to a single color when the disc is spun, the blend in this case appearing orange. The complementary relationship is established when

the blend appears a neutral gray. Ostwald chose “a pure yellow that is neither greenish nor reddish” [20, p. 33] as the starting point for his hue sequence. This would correspond to the elementary yellow of Hering and the NCS but the complementary of this yellow, as established by the spinning disc technique, is not quite a blue that is

Color Circle,

Fig. 11 Color circle by Wilhelm Ostwald.
(Reproduced from Ref. [6], with permission)

neither reddish nor greenish but one that is slightly reddish which Ostwald identifies as “ultramarine blue.” Similarly if Ostwald’s fundamental red is neither yellowish nor bluish, its complementary is what Ostwald calls “sea green,” a green that is certainly bluish. So Ostwald’s four fundamental colors are not the exact equivalent of the Hering/NCS elementary colors. And Ostwald, unlike those who developed the NCS, did intend his system to be used for generating harmonious color combinations for application in the arts and design. For Ostwald his system represents “order” and he is famous for his “basic law”: “Harmony = Order” [20, p. 65].

Müller

Ostwald’s ideas were taken up and developed by Aemilius Müller who produced his *Swiss Colour Atlas* using dyes rather than pigments. Müller’s color circle has 60 hue steps (Fig. 12). Müller also produced a number of designs with beautiful color gradations to demonstrate Ostwald’s “basic law.” Müller’s work is described by Stephanie Wettstein [21, pp. 144–149].

The CIE Chromaticity Diagram

Although not geometrically circular, the 1931 CIE chromaticity diagram can be regarded as a color circle in that it represents the pure spectral hues and the extra-spectral purples in a continuous sequence. The diagram is used in the international system for measuring color stimuli. The diagram is often shown in color but Roy Berns warns against this as being misleading [22, p. 61]. No printing inks can match the purity and intensity of the spectral lights themselves. It is better simply to show the line diagram marked out with color names, such as those proposed by Kenneth Kelly [23, p. 67], much as Newton did with the first color circle. The CIE diagram, with Kelly’s names, is shown in Fig. 13.

Munsell

Albert Henry Munsell developed his color system at the turn of the twentieth century and published *A Color Notation* in 1905. Munsell’s color circle has “five principal hues” [24, p. 20]. These are red, yellow, green, blue, and purple, which are spaced at equal intervals around the circle. In his

Color Circle,

color names proposed by Kenneth Kelly

sequence of hues, Munsell aimed at perceptual uniformity [2, p. 115]. Like Ostwald, Munsell believed in an ordered arrangement of colors as the key to harmony and suggested a number of paths through his system that would connect

colors for a harmonious result. Figure 14 shows a page from the 1929 edition of the *Munsell Book of Color*. Twenty hues are included, each at several steps of increasing departure from neutral gray. Use of the CIE system to measure the Munsell color chips revealed a number of irregularities. A combination of instrumental measurement and visual judgments by members of an expert committee resulted in the Munsell renovations and the revised Munsell system that is widely used today.

The Color Circle Today

Today there are color circles in use that are based on three, four, and five primaries, but the three-primary model remains dominant with the primaries red, yellow, and blue; the secondaries orange, purple, and green; and 12 hues altogether. This is born out by an appeal to the Internet. Of the first 100 images from a Google search, made on

Color Circle, Fig. 14 Color circle from the 1929 edition of the *Munsell Book of Color*. (Reproduced from Ref. [6], with permission)

December 7, 2013, more than half were twelve-hue circles and nine of these were the circle designed by Johannes Itten with primaries and secondaries identified in the center (Fig. 15).

Itten

Itten's circle is attractive, clear, and memorable, but it needs to be viewed with caution. Itten was an artist writing for students of art. Artists work

with pigments and so the “color classification must be constructed in terms of the mixing of pigments” [25, p. 21]. But Itten defines his primaries in terms of appearance: “a red that is neither bluish nor yellowish; a yellow that is neither greenish nor reddish; and a blue that is neither greenish nor reddish” [25, p. 29]. Itten refers to green in these definitions, as does Hering in his definitions of *urfarben*, and green is one of the elementary colors of the NCS. Nevertheless, for

Color Circle, Fig. 15 Color circle by Johannes Itten as reconstructed by Lisa Hannaford

Itten, green is a secondary color, a mixture of blue and yellow.

From the experience of working with a number of different paints, it is possible to judge, from their appearance, how useful a group of paints will be in the mixing process. Students can be misled by the Itten diagram and may blame themselves if they are unable to mix a satisfactory range of colors from red, yellow, and blue primaries as these are defined by Itten. As Harald Arnkil points out, “anyone who has tried to create Itten’s twelve-hue color circle according to his requirements will be frustrated to a lesser or greater degree” [26, p. 88]. A more satisfactory range of colors can be mixed with paints that are closer in appearance to the cyan, magenta, and yellow inks as used by printers. This is demonstrated in the entry on ► [“Primary Colors”](#) in this encyclopedia.

Itten’s color circle (Fig. 15) was recreated for the present entry by Lisa Hannaford using the computer program *Illustrator*. As displayed on the computer screen, Itten’s diagram is created with the additive primaries red, green, and blue. When printed in hard copy, for Itten’s book as well as from the computer file, the inks used are the subtractive primaries cyan, magenta, and yellow. The relationship between the additive primaries

and the subtractive primaries are shown in a color circle first presented at a conference in 1978 [27, p. 167, 28, p. 3 and cover] (Fig. 16). For this diagram, cyan is identified as turquoise, which is a more familiar color name. A shape code identifies the additive primaries as circles and the subtractive primaries as squares.

Perhaps Itten could have acknowledged the shortcomings of available pigments and followed the example of Moses Harris by explaining how he “treats on colour in the abstract.” If the diagram is misleading as a guide to mixing paints, it is reasonable to wonder what purpose it is intended to serve. Arnkil asks this question and suggests that it may have been “associated with his idea of the 12-colour circle as the basis of colour harmony” [26, p. 88].

Itten follows Goethe in asserting the significance of the afterimage phenomenon for color harmony, and he claims that opposite colors in his circle are complementary. Harmonious color combinations can supposedly be found by drawing a regular geometric figure inside the circle. Lines passing through the center of the circle, equilateral triangles, isosceles triangles, squares, and rectangles, as they touch the colors in the circle, all point to harmonious color combinations. As well as complementary pairs, Itten illustrates harmonious triads and tetrads – combinations of three and four colors. No doubt this is a useful starting point for people who lack confidence, but closer scrutiny reveals a problem. Itten defines complementary relationships in three ways, all of which have been encountered in the work of others: subtractive mixing to near black (Harris), afterimages (Goethe), and additive mixing to neutral gray (Ostwald). The theory would be more convincing if these different ways of defining complementary relationships yielded the same pairs, but this is not always the case. The most dramatic variation is with blue. The complementary of blue is red-orange from subtractive mixture, yellow-orange as an afterimage, and yellow from additive mixture. If these pairs are to be opposite to each other in different circles, the distribution of hues would need to be adjusted.

ture to neutral *gray*

An Elastic Color Circle

Complementary relationships, as established in
different ways, can be illustrated by stretching
and compressing the color circle [29, p. 266].
With the elementary colors of the NCS as refer-
ence points, and by keeping yellow and red

constantly at 12:00 o'clock and 3:00 o'clock,
respectively, blue and green can be moved to
new positions. The number of hue steps between
the elementary colors will increase or decrease
accordingly to bring the differently defined com-
plementary pairs opposite to each other as shown
in Fig. 17.

Conclusion

The color circle has a long history and is well established in color theory. It is used to represent colors as something physical, as lights, pigments, inks, or dyes, as well as colors as visual phenomena. It is used to illustrate relationships between colors, in systems of color classification and identification, as a guide to mixing and as a tool in the search for harmonious color combinations. Although the sequence of hues is always the same, the intervals between hues can vary as the principles behind the construction of the circles varies. There is no single color circle that is “correct.” Rather than try to establish a single color circle as some kind of standard, or to insist on a single purpose for the color circle, it is more helpful to recognize that a color circle can embody a variety of information and that it may be necessary to stretch or compress the hues in the circle according to the information that is required.

 Buenos Aires, Argentina

Synonyms

Color coordination; Color harmony; Color mixture; Color syntax; Color union

Definition

Color combination is mainly an aspect of color syntax. To combine means to put one thing in relation to another, or several things together, so that the individuals lose significance and the meaning of the whole predominates. To combine also means to organize an ordered sequence. In some cases, it acquires the sense of mixing or merging. However, mixing color pigments or lights normally yields just one color as the result of the mixture, and in this sense, it cannot be termed a color combination, for which two or more colors in some relation must be perceived.

Combination certainly is very closely connected to harmonization and coordination. Color combination, thus, is meant whenever there is more than one color associated, related, or harmonized with another: Two colors already determine a certain kind of combination.

Overview

Color combination is, in principle, an aspect of color syntax. All perceptible colors can be organized in the so-called **color order systems** or models. This is usually made by means of three color variables or dimensions, for instance, hue, saturation, and lightness (HSL), or hue, blackness, and chromaticness (according to the Natural Color System), or hue, value, and chroma (according to the Munsell color system), or some other similar triad of variables. These color order systems allow for the precise identification and notation of colors and their arrangement in a logical way. Some of the systems even allow predicting the results of color mixtures. It is possible to compare color order systems to dictionaries, which assemble all the words available in a language in alphabetical order. Therefore, color order systems arrange and organize all the colors that humans can see, produce, and use, according to certain sequences determined by the mentioned color variables.

This possibility of having the repertoire of all perceptible colors orderly arranged facilitates the selection of colors, by following certain criteria, in order to use them in artistic compositions, architectural works, or pieces of design. Only in few rare occasions (for instance, in experimental situations) colors are seen isolated; in the great majority of cases (both in nature and in human productions), colors appear in a context where there are also other colors. That is to say, every color is combined in a certain way with other colors. Such as words (which in a dictionary appear isolated) are combined with other words in order to make sentences with some sense and give origin to poetry, narrative, essay, etc., and in the same way as sounds are combined by a music composer to give origin to musical pieces, so

colors are grouped in larger compositional units. It is the context, the particular combination, the way in which colors are grouped together and related to one another, what gives a certain kind of signification or meaning, some utility to the whole composition and to each of the involved colors.

Painters dispose and mix colors in their ► **palette** with the final aim of combining them in a canvas. Architects combine materials with different natural colors in a building or use paints to endorse different parts of their work with color. Filmmakers and directors of photography decide about the color sequences that appear in successive scenes of the film. Clothing and fashion designers think about the chromatic combinations of the apparels they produce. Landscape designers choose and arrange the botanical species and other materials taking into account also color combinations. It is possible to continue providing this kind of examples almost indefinitely, because there is practically no profession, discipline, or human activity in which color does not play a role.

If according to different authors and experiments, the number of perceptible colors may range, depending on various factors, from 2,000,000 to 7,000,000, the combinatorial possibilities rise to billions, even restricting them to the minimal expression of just two- or three-color combinations. Now, how are colors combined, with which kind of criteria, and in which type of contexts? At first, it is possible to talk about spatial and temporal contexts, depending on the colors being arranged simultaneously in an object or successively in a certain temporal sequence.

Syntactic Color Combinations

Spatial Color Combinations

The spatial color combinations have, at first, some basic and elementary rules. In terms of the abstract and logical possibilities and from the point of view of spatial arrangements, three possible cases can be pointed out for two-color combinations in a two-dimensional space:

1. That one color is applied over and inside another (interiority).

2. That both colors partially overlap each other (overlapping).
3. That they are juxtaposed one beside the other (juxtaposition).

The possibility of both colors being some distance apart is not considered here because in this case the color filling the separation, the background, appears as a third color. In addition, there is no sense in considering a total superposition of both colors (both occupying exactly the same space), because in this case the result is just one color, and hence, this cannot be termed a color combination.

These three possibilities produce different results or have different consequences for color light and for color-pigment combination and also differ if there is a mixture or blending of the involved colors or if opaque color surfaces that do not mix together are combined. Combining colors imply that in some cases the colors are mixed and give origin to new colors. However, if the result of the mixture is just one color, this will not be a color combination.

For instance, considering transparent color filters:

1. If over an area of a transparent color filter *A* another piece of color filter *B* is set in relation of interiority, the outcome is two colors: color *A* and a new color, *C*, which is the subtractive mixture of *A* and *B*, while color *B* is missed.
2. If the colors overlap, the result is three colors: *A*, *B*, and *C*.
3. In the case of juxtaposition, there is no color mixture, so that the result is color *A* just besides color *B*.

These combinations with their respective results are shown in Fig. 1.

The same happens with transparent inks and watercolors. Similar situations arise also when *A* and *B* are colored lights, but in this case color *C* is the result of an additive mixture. The situations are quite different with opaque color surfaces: In all cases, no new color *C* appears.

Additionally, in all situations – interiority, overlapping, and juxtaposition – phenomena of

Color Combination, Fig. 1 Basic possibilities of two-color combinations in a two-dimensional space

simultaneous contrast occur. Thus, considering colors *A* and *B* in isolation, the perceptual result of their combination is colors *A1* and *B1* (apart from the cases in which color *C* appears), because each color is tinged with the complementary color of the other, according to the principles of simultaneous contrast. That is to say, color sensations change from seeing color stimuli in isolation to seeing color stimuli in combination.

Now, if the combined colors have relatively small areas to be perceived individually, three situations may arise: (1) An additive mixture is produced when they consist of small pixels or cells of color light (as in the case of the TV screen). (2) A partitive mixture occurs when they are small dots of surface colors (as with the pointillist technique of painting). And (3) a mixed syntheses occur – partially subtractive and partitive – if the small dots are made of transparent inks that in some zones overlap each other and in some others are separated on the background (as in the case of color printing).

The variation in relative size of two color fields may produce two opposite perceptual phenomena: color assimilation (or color spreading effect) and simultaneous color contrast. Let us have an alternating sequence of two color strips, for instance yellow and gray, with different relative widths. When the yellow strip is wider than the gray one, a simultaneous contrast occurs, and the gray stripes are perceived as tinged with the complementary color of yellow, and look bluish (i.e., more dissimilar to yellow). When the yellow stripes are very thin lines on the gray background an assimilation is produced, and the same gray

looks now yellowish (i.e., more similar to yellow), when viewed from an appropriate distance (Fig. 2). Actually, in Fig. 2b the yellow thin lines start to blend with the gray background or spread over it because we are approximating a partitive or optical mixture. Color contrast increases the difference between two colors, while color assimilation increases the resemblance between them, and the appearance of one phenomenon or the other depends on the relative size of two combined colors.

Another aspect concerning the relative size of combined color fields is the role that certain colors play in a design. In three-color combinations, the following categories are usually distinguished: dominant or main color, secondary or subordinate color, and accent color (Fig. 3). In architectural facades, interior decoration, clothing, and other branches of design, an empirical rule is often applied: approximately 60% of the surface is given to the dominant color, around 30% is left for the secondary color, while the accent color takes the remaining percent of the total surface (around 10%). In general, high saturation or chromaticness is used for the accent color, while the dominant and secondary colors are usually less chromatic. In addition, a complementary contrast of hue is often used between the accent color and the dominant and secondary pair. The key is to create a contrast in terms of lightness, saturation, and hue.

Temporal Color Combinations

Phenomena of contrast appear whenever two or more colors are combined in a certain relation, but

Color Combination, Fig. 2 Different proportions in the combination of two color stimuli may produce simultaneous contrast (left, where the gray looks bluish) or

assimilation (right, where the gray looks yellowish). Note: Both gray stimuli are equal to the horizontal stripe above

if this is a temporal combination, where the colors appear in a sequence, with certain durations and intervals, what is produced is a successive contrast or the phenomenon of post-image.

When the time span of visualization of a color followed by another is long enough, an adaptation to the first stimulus occurs, and, therefore, the second stimulus is affected by the successive color contrast.

When the frequency of appearance of two or more colors is fast enough to fall below the perceptive threshold (as in a flickering situation), an optical mixture of the colors involved in the sequence will be produced. It also happens here that two or more colors combined in these conditions give only one color as a result, the color that is the consequence of the optical mixture.

Color Selection as the First Step for Harmonic Color Combinations

If some specific chromatic relations among the combined colors are taken into account, the field of [color harmony](#) appears. There are a lot of proposals and theories about this. From a purely

syntactical point of view, paying attention to the relations among the colors themselves and the quantity of colors combined (two or more colors), it is possible to mention, for instance, a combination of monochromatic colors, complementary colors, split complementaries, double complementaries, analogs, color triads or trichrome combinations, tetrachrome combinations, etc.

César Jannello proposed criteria to select colors to be applied in a combination. Starting from the three color variables or dimensions – for instance, hue, saturation, and lightness – there are just eight possibilities for the selection of colors, whether these variables are kept constant or change. In Fig. 4, the sign plus (+) means constancy, and the sign minus (–) represents variation of the considered dimension. The first formula, the one in which everything is constant, is not of much use because it gives as a result the selection of just one and the same color. In the remaining formulas, where some type of variation appears, the interval of variation may be constant or may change according to some criterion, for instance, by modifying hue, lightness, or

Color Combination, Fig. 3 (a) Three-color combination in dress: blue 66% (dominant color), cyan 26% (secondary color), red 8% (accent color). (b) A facade with a three-

color combination: yellow 60% (dominant color), white 30% (secondary color), red 10% (accent color)

saturation in regular steps or intervals, by increasing intervals, by choosing opposite poles, etc. This model provides a logical basis to select and combine colors for design purposes.

A Theory for Colors in Combination

Anders Hård and Lars Sivik [1] have settled the basis for a theory of colors in combination. They have developed a structure that considers three dimensions or factors that are useful to describe or analyze color combinations: (1) *color interval* (dealing with color discrimination and having distinctness of border, interval kind, and interval size as subvariables); (2) *color chord* (dealing with color identification and having complexity, chord category, and chord type as subvariables); (3) *color tuning* (dealing with how color combinations can be varied and having surface relations, color relations, and order rhythm as subvariables).

Figure 5 shows an outline of this model, published by Hård in 1997 [2].

This model for color combination was worked out along various years, and during its development their concepts, dimensions, and subvariables were changing to some extent. Hård and Sivik published previous formulations of this theory in 1985 and 1994 [3, 4]. In some of these, for instance, the visual context in which the color combination appears is considered as a fourth and very important factor.

Semantic and Pragmatic Aspects in Color Combinations

At the beginning of this article, we have said that the combination of colors is mainly a syntactical aspect. But since colors have a semantic weight,

Color Combination, Fig. 4 One example of Jannello’s criteria for selecting colors to be used in a color combination

produce emotions, have meanings, are used as signals, indicate situations, propose behaviors, communicate messages, etc., and all this can vary according to the way in which colors are combined and according to the context, it is also possible to consider color combinations from a semantic point of view.

Here is a simple example. The three colors of the traffic lights (red, yellow, green) are a spatial and temporal syntactical combination, on one side. They make a triad of separated color lights, displayed in a circular shape, that appear with a spatially codified vertical arrangement: red at top, yellow in the middle, and green below. The temporal sequence is also regulated and codified: yellow comes after green and red comes after

yellow. The step from red back to green is normally direct, without intermediation of yellow, and the same sequence appears again: green, yellow, and red. The size of each color has also a specific relationship: the red circular light has a larger size than yellow and green. The same happens with the time interval or duration in which each light is displayed: yellow appears for a brief instant, while red and green have longer durations. Now on, all these are purely syntactic aspects. Nothing has been said yet about what meaning this selection, arrangement, and sequence of combined colors conveys. By entering in the semantic domain, it is possible to talk about the codification of those three colors in that particular context of use. Red means “stop,” green means “go,” while

Color Combination, Fig. 5 Outline of a color combination model by Anders Hård [2]

yellow is a warning about the change of light from green to red that is coming soon and imply that the user has to take the necessary caution, either apply the brakes to stop the vehicle or speed up the march to make it through before the red light appears.

Thus, there are also semantic issues that are combined from a syntactical arrangement of colors and the context in which they are used and interpreted. The same red color used for the traffic lights may have very different meanings in other contexts. It may connote emotions such as passion, love, and rage. It may indicate something that is important to notice and deserves to stand out (a red typo in a context of black letters and words). It means expulsion from the field in the context of a football (soccer) match. It may also connote speed or status in a car (a red Ferrari), etc. Hence, it is the context (either the social, cultural, geographic, or temporal context in which the colors appear, as well as the relationship with other colors that are in the same context or situation) what endorses colors and color combinations with a certain sense or meaning.

Color combinations have been studied from the semantic point of view by various authors. Elda Cerrato points out the basic concepts behind the idea of color combination, discusses some

color order systems and color harmony theories related to this (mainly Ostwald, Munsell, and Arnheim), and addresses the issue of how culture conditions harmonies, preferences, and aesthetical principles of color combinations [5].

Shigenobu Kobayashi, working at the Nippon Color and Design Research Institute, has devised a method to classify single colors or three-color combinations by their associated images [6, 7]. Through the analysis using the axes warm/cool, soft/hard, and clear/grayish as coordinates, this method, which was also extended and developed with some collaborators [8, 9], can plot climatic and cultural differences in color semantics. In 1997, Kobayashi and Iwamatsu extended the color combination research to be able to include five-color combinations [10], even when from the countless number of possible five-color combinations they chose to make the survey by selecting 20 pairs of contrasting combinations of five colors (40 color combinations in total). To justify that particular research, they point out that “a five-color combination makes it easier to gain a psychological understanding of scenic conditions and convey the sense of ambience than two- and three-color combinations.”

The book by Hideaki Chijiiwa, from the Musashino College of Art, at Musashino Art

University, intends to be a manual for choosing color combinations for different purposes, taking into account meanings and mood [11]. For practical applications in art, design, industry, or everyday life, it provides a guide for selecting two-, three-, and four-color combinations associated to adjectives such as striking, tranquil, exciting, natural, warm, cold, young, feminine, and surprising. As for the quantity of colors to be employed in a combination, the author advises to limit them to two or three. A warning is made when using four-color combinations that should be selected very carefully, while five-color combinations are directly discouraged. The book by Bride M. Whelan continues in the same venue [12].

Lars Sivik (working sometimes in collaboration with Anders Hård and Charles Taft) carried out research on the meanings of color combinations [13–15]. The descriptive model uses the Natural Color System as a basis, and the methods are aimed at studying the stability and variability of color-meaning associations across time and cultures. These studies “literally mapped the world of color with respect to how associations to various words systematically vary across different parts of the color world.” In the research published in 1989, Sivik selected 130 words by a semantic differential scaling method, and the subjects judged color images as “to how well the different word went with the color composition in question” [15]. The main purpose was “to obtain a small number of variables that would be reasonably representative of all color describing variables.”

Other authors have also used the semantic differential method to study the meanings of color combinations, and more specifically their affective values, by applying this tool to two- and three-color harmonies [16, 17].

Colors, in general, and color combinations, in particular, can be considered as a system of signs. They certainly have syntactic aspects (which include both the elements and the combinatory), semantic aspects, and pragmatic aspects that imply the use of these signs by the interpreters. In previous publications, the author of this entry describes and illustrates various semiotic concepts with examples taken from color theory and

provides an account of some of the advances of color theory within the framework of semiotic categories [18, 19].

Some color theorists go even beyond these considerations, proposing that colors and color combinations can be taken as a language, for instance, Luckiesh in 1918 [20], Sanz in 1985 and 2009 [21, 22], Oberascher in 1993 [23], as well as Hård in the already mentioned article published in 1997 [2]. However, this should be taken with certain caution. Human languages (for instance, verbal languages, English, Spanish, French, German, etc.) serve not only for communicational purposes but also for cognitive and modeling purposes; they allow to build categories, models, and theories about the world, in order to understand it, explain it, and make it meaningful for the human species. If it is possible to demonstrate that color combinations can have a similar status, then the color-language idea will be more than just a metaphor.

Color Constancy

Bei Xiao

Department of Computer Science, American University, Washington, DC, USA

Definition

Color constancy refers to the ability of the visual system to perceive stable object colors, despite spatial and temporal change, as well as spectral changes, in the illumination. It is a prime example of perceptual constancy [1]. In daily life, humans and animals often count on color constancy to identify, discriminate, and search objects, as well as to judge physical and functional properties of objects. In a related concept, in machine vision, white balancing algorithms in cameras and image acquisition systems are widely used [2, 3]. Color constancy has been an active research topic in the past 100 years. For a thorough understanding of this subject, please see the following recent reviews and papers [4–15].

Human Color Constancy

Figure 1 shows photos of the same scene under two illumination conditions. The left photo was taken in the morning when the dominant light source is the daylight, while the right was taken in the evening when the dominant light is tungsten light. If one were in the scene, one would perceive the teapot under both illumination conditions to have the same colors, though individual pixels from the same location from the teapot and the banana in the two photos appear very different (see the patches above the photos). This is also similarly demonstrated by Kitaoka's Twitter account on a red tomato viewed through a green filter. The research question of human color constancy is whether and how the visual system can disentangle the two sources of information, illumination spectrum and surface reflectance, to identify surface colors.

Results of Human Color Constancy Measurements

The visual system generally exhibits high level of color constancy under natural illumination

likely due to its ability to adapt to the environment [16]. However, laboratory measurements of magnitudes of color constancy showed large variation of color constancy measurements in the last 30 years and indicate it is rarely perfect [6, 17–19], for a recent review see [14]. Previous work discovered that instructions and tasks affect the degree of color constancy [20–22]. The articles state that asymmetric matches with appearance-match instructions tend to yield particularly low color constancy indices. The studies that yielded near perfect color constancy (90%) either guaranteed in some way for adaptation [23–26] or used naturalistic scenes where many cues that are available for inferential constancy [27, 28]. Cognitive factors have also been considered in studying color constancy [29–32]. Some objects have characteristic colors, such as bananas are yellow and cucumbers are green. Though previous work shows constancy improved with familiar objects [31], a recent work by Kanematsu [33] suggests the effect of familiar contextual objects on color constancy is small. In Fig. 1, for example, the color of the banana seems stable across the two illuminations. This might be due to our prior knowledge of the object's color.

Color Constancy, Fig. 1 Photographs of the same scene lighted under two illuminants. Left image: Window daylight. Right image: A mixture of indoor artificial lighting sources. The photographs are taken by a Sony Cyber Shot DSC-WX350 compact camera with white-balance turned off. Top panel: the patches show rectangular regions filled with the color from roughly the same locations of the objects in the two images. Bottom panel: the images from which the patches were extracted. Notice

that most objects in the scene remain color constant, though the color patches indicate dramatic change in pixel color. However, material properties such as the specular surface of the teapot do influence the degree of color constancy (most people would agree that the teapot in the left image appears bright blue but grayish blue in the right image). The example also shows familiarity of the object (e.g., banana) helps achieve better constancy

Color Constancy, Fig. 2 Failures of color constancy. Left: A photograph of fruits taken under a monochromatic low-pressure sodium light. Right: The same scene was illuminated by normal broadband light sources. Most observers

won't be able to tell the color of the bell pepper from the left image. But such monochromatic light source is rare in the real world

Under suboptimal lighting (e.g., narrow-band lighting), constancy can also be poor under certain conditions. Figure 2 illustrated a scenario where color constancy fails for most observers. In sum, color constancy is high in natural settings where many cues that allow for a successful inference.

Cues of Color Constancy

Figure 3 demonstrates that color constancy is an ill-posed problem. Reflected light is a function of both illumination and surface reflection. How can the human visual system disambiguate the contribution of the two and achieve constancy? It was shown that humans might use a variety of different image cues about color constancy that are available in different experiments (see reviews [6, 10]. Adaptation and simultaneous local contrast are the major mechanisms that allow for constant color appearances across illuminations. Human observers can also infer color by comparing colors across illuminations that serve as references or anchors. This information can be obtained from depth and motion information [34], specular highlights [35–37] and 3D inter-reflections, shading [38, 39], and memory colors [40–43].

Color Constancy, Fig. 3 Illustration of color constancy. The spectrum of reflected light reaching the eye, $C(\lambda)$ is a wavelength by wavelength product of surface reflectance S and the illuminant E . The problem of color constancy is challenging because different combinations of illumination and surface reflectance can result in the same color signal. This illustration is adapted from Brainard and Radonjić [98]

Constancy Across Surface Colors and Illuminations

Measures of color constancy can change depending on the surface color [18, 31]. Also,

recent works studied the relationship between illumination discrimination thresholds and color constancy and found color constancy depends on the illumination color [44]. They proposed illumination discrimination as a useful new measure of color constancy under different illuminant colors [19]. The consensus of these findings is that observers have a blue bias: they are less sensitive to changes toward the blue direction of the daylight (see [15] for a review and [45–47]), meaning that the measured threshold of illumination discrimination is highest in a bluer chromatic direction. This bias suggests that color constancy might be adapted to daylight illuminations and shadows. Since representation of illumination is closely entangled to representation of surface reflectance at the proximal image, accuracy of estimating illumination of the visual system may directly affect accuracy with which it represents surface reflectance. Accuracy might be higher or lower depending on which direction the illumination change happens. Previous work found that illumination discrimination depends on illumination change direction [48] and the ensemble of surface reflectance in the scene [46].

What Do we Know about Neural Processing of Color Constancy?

Human neuroimaging studies show that responses to color already happen in early areas V1 and V2 [49–51]. Outside area V1 and V2, earlier investigation demonstrated the involvement of area V4 in color perception in monkeys [52, 53] and area IT [54]. However, following these initial works, other studies failed to find clear evidence that V4 was any more involved in color processing than areas V1 and V2 [55]. Recent work in fMRI and micro-electrode recording tried to solve this controversy. The results show that area V4 has a mesoscale organization comprising millimeter-sized color-biased regions, dubbed globs, which have many color-tuned neurons, interspersed with inter-glob regions that have much less color-sensitive neurons (for more details, see [56]). The controversial results are likely caused by recording from neurons at different locations

from area V4. Using physically realistic rendered scenes and multi-voxel pattern analysis, Bannert [57] found only in V1 and V4 surface color representation that is invariant across illumination changes. They also found that along the visual hierarchy, there was a gradient from V1 to V4 to increasingly encode surface color rather than illumination. Even though these studies shine some lights on brain areas involved in color constancy, its neural mechanism is far from understood. One challenge is mapping different sets of psychophysical measurements of color constancy onto different stages of the neural color processing stream. Another challenge is that color constancy might depend on spatial integration of reflected light across surfaces that likely involve many brain areas.

Theories of Human Color Constancy

Can we predict constancy in complex scenes mentioned above? One approach to understand constancy is to explain it using low-level visual mechanisms such as chromatic adaptation. Von Kries proposed that the LMS cone signals are scaled by a multiplicative factor, and at each retinal location, the gains are scaled independently [58, 59]. For each cone class, the gain is set in inverse proportion to the spatial mean of the signals from the cones of the same class. This algorithm is called von Kries adaptation. There are many models developed for color constancy based on cone adaptation models such as the Land's famous retinex theory [60], which has very wide application in camera color balance and can be used to explain human color constancy for the flat-matt-diffuse stimuli. The central principle of the retinex theory is that the lightness values at each pixels are calculated independently for each cone class. For an analysis of the retinex theory and color constancy, see a study by Brainard and Wandell [61]. The adaptation models predict color constancy quite well for flat and mat and diffuse scenes. However, it often fails to predict constancy for rich scenes as mentioned above [16]. We do now know how to obtain the values of the multiplicative gain from images,

which contain spatially rich information. Another approach is to develop computational models that could be used to predict human color constancy in complex scenes. The *equivalent illuminant model* assumed that the only error the visual system makes in an attempt to achieve constancy is that it misestimates the scene illuminant [62]. In a Bayesian framework, Brainard and Freeman [63] constructed prior distribution that describes the probability of illuminants and surfaces in the world, and then estimates the illuminant from the posterior distribution conditioned on the image intensity data. Further studies applied the similar Bayesian model to predict the degree of human color constancy across different manipulations and connect the variation in constancy to the prior distribution of the illuminant [64, 65].

#TheDress and Individual Variations in Constancy

In 2015, on the internet a photo of dress (#theDress) became a viral social media sensation with viewers disagreeing whether the dress is blue or black, or white and gold. A large proportion of observers saw the colors of the body of #theDress as blue and the lace black, while some others saw them as white and gold [66–68]. Even though there is currently no consensus on why the dress elicits such a discordant color perception among the viewers, there have been many scientific articles published proposing the role of illumination estimation on the individual perception [69–72]. It was found that the perceived colors of both body of the dress and the lace as well as the physical pixels of the body of the dress and the lace were distributed in a continuous range of hues close to the daylight locus [69]. This alignment of the pixel color signals in the image makes it possible to attribute the color variation either to the fabric or to the lighting conditions. The assumption about the illumination is different between observers. Some observers implicitly assumed the dress to be in the shadow, implying bluish-dark lighting, and they saw #theDress as white and gold. In contrast, some observers believed the lighting to be white and bright and saw #theDress as blue and black. The variation of the pixel colors

along the daylight locus could contribute to the magnitude of individual perceived differences. In addition to explain the phenomena in the light of illumination estimation, there is a strong interaction between illumination, material properties, pigment of the fabric material, and color constancy. Fabrics interact with light in complex ways, and this might affect the degree of color constancy [73]. Overall, the phenomena of #TheDress intensified the discussion of the plausibility that the neural mechanisms underlying color constancy are optimized for illuminations along the daylight locus [74]. It also raises attention to the role of the interindividual variability in color constancy.

Machine Color Constancy

While the human visual system is equipped with good color constancy in most situations, the digital camera has to rely on color-balancing algorithm to discount the illumination effect and extract the invariable object color. This process is also called color balance or white balance. “Color constancy” means recovering the vertical world behind an image, while “white balance” means giving the image pleasant appearance by discounting the effect of illumination that is consistent with some aesthetic norm. The vast majority of computational color constancy research is focused on illumination estimation. The methods can be divided into two categories: statistics-based method and learning-based.

The best-known statistical method is the gray-world theory, which assumes that the average reflectance of a scene is gray [75]. Some other similar algorithms include white patch and max-RGB [76], and shade of gray [77]. The gray-world algorithm will fail if the average reflectance is not achromatic or if there is a large uniform colored surface in the scene. The incorporation of higher-order statistics in terms of image-derivatives is proposed, where a framework called gray edge is presented [78].

Learning-based methods estimate the color of illuminant using a method learned from training data with labeled ground-truth. Chakrabarti [79] et al. go beyond statistics of per-pixel colors and

model the spatial dependencies between pixels by decomposing the input images into spatial sub-bands, and then model the color statistics separately in each sub-band. Forsyth [80] introduced the gamut mapping method. It is based on the assumption that only a limited set of colors (canonical gamut) can occur under a given illuminant. The model learns a model based on training images (the canonical gamut) and estimate the illuminant based on the input features. Inspired by Brainard [63], Rosenberg et al. [81] introduced a Bayesian model of color constancy utilizing a non-Gaussian probabilistic model of the image formation process and demonstrated that it can outperform the gamut-mapping algorithm. Gehler et al. [82] extended the Bayesian algorithm using a new dataset, which allows the algorithm to learn more precise priors of the illuminations. Barron [83] developed the Fast Fourier color constancy algorithm that can be readily used on a mobile device with 700 frames per second. The algorithm is based on estimating a complete posterior distribution of illumination instead of a single illuminant.

Many of these models were trained on hand-crafted features extracted from the input image [84–87]. For example, Bianco et al. [88] proposed a novel model to estimate illuminant from color statistics extracted from faces automatically detected in the image. It takes advantage of the fact that the skin color tends to cluster in the color space, which provides a valid cue to estimate the illuminant. Inspired by human visual system mechanisms, a recent study by Gao et al. [89] built a physiologically based color constancy model that imitated the double-opponent mechanism of the visual system. The illuminant is estimated by searching for the maxima of the separate RGB channels of the responses of double-opponent cells in the RGB space.

The most recent learning-based models learn features by using deep convolutional neural networks (CNNs). Bianco et al. [90] was the first to use a CNN to learn discriminant features for the illuminant estimation task and similar deep learning-based color constancy algorithms were developed [91–94]. The challenging of the deep learning-based methods is the requirement of large-scale datasets with ground-truth illuminants

and the current largest datasets for color constancy are much smaller than those of object recognition. To solve this issue, several unsupervised learning methods in the neural network framework has been proposed that does not need such as labeled database. Qian et al. [95] proposed a statistical color constancy method that relies on a novel gray pixel detection followed by mean shift clustering. Bianco et al. [96] trained networks to detect achromatic pixels after the images are converted to grayscale as a proxy of illuminant estimation and then used this estimation to perform the white balancing. A new work avoided to explicitly estimate illumination but proposed an algorithm that corrects a camera image that has been improperly white-balanced [97]. The data-driven approach takes an incorrectly white-balanced sRGB image and computes a mapping that can transform the input image's colors to appear as if the white balance was correctly applied.

Future Directions

Color constancy is an important and practical problem in both human and computer vision. Color constancy provides an excellent model system to understand how the visual system solves ambiguity. Significant progress has been made to understand color constancy of simple scenes. A big challenge is how to extend the theoretical model of color constancy for simple scenes to predict human performance in rich scenes and explain individual variabilities. How color is encoded in the cortex is still a major scientific question. Mapping different types of psychophysical measurements of color constancy onto different neural processing stages and streams is challenging. The current experimental evidence suggests that color information is encoded throughout the visual cortex and it is possible that color constancy is variously represented.

Major breakthroughs in computational color constancy algorithms have been made thanks to development of large datasets and machine learning methods. However, it is unknown whether or not the human visual system uses similar algorithms to achieve constancy and how to improve white balance algorithm based on human color

constancy. How to bridge the two fields is a promising endeavor for future research.

Definition

Color constancy is defined here as the ability to identify surface color across variations in ambient illumination or scene context. Presuming that an important function of color vision is to help identify objects and object properties based on surface color (e.g., ripe fruit, fresh fish), stable appearance is not a necessary requirement, as long as the percept is sufficiently constant for color identification. One aspect of color perception that may be relevant here is the ability to classify colors into a small number of categories; it may be sufficient for color identification across illumination changes to maintain constancy of color categories.

Color Constancy

The Problem

Color perception is a computational challenge because the light reaching the eye confounds information about the stable surface property that we care about – surface reflectance – and the ambient illumination. This is compounded by the fact that the light spectrum is encoded into three quantities in a trichromatic retina, that is, in the activations of the long-wavelength-sensitive, middle-wavelength-sensitive, and short-wavelength-sensitive cone photoreceptors (Fig. 1; [1]). It is not possible, without additional constraints, to recover the spectral reflectance from the light signal because of an infinite number

Color Constancy and Categories, Fig. 1 The problem of color constancy. (a) Each surface has a spectral reflectance, which indicates how much light is reflected at each wavelength of the visible light spectrum. Reflectance is a stable object property, which correlates with perceived surface color. (b) Each illumination has a power spectrum which indicates how much energy it has at each wavelength. The panel shows the power spectra of two daylight

illuminants, a bluish skylight and a yellowish sunlight. (c) The power spectrum of the light that reflects to the eye from a surface is a product of its reflectance with the illuminant power spectrum. (d) The light signal is coded with three quantities in a trichromatic retina – the l-, m-, and s-cone photoreceptors. Perceived color categories may remain more stable under illumination changes than color appearance

of possible combinations of spectral reflectance and illumination. The severity of this problem may surprise the reader considering that we rarely notice any significant “errors” in color perception in our everyday lives, except perhaps under extreme or unusual illumination changes. This is despite the fact that the reflected light from a surface varies considerably even under moderate illumination changes (see Fig. 1c–d).

Measuring Color Constancy

Color constancy has traditionally been characterized by measuring the appearance of small stimuli on uniform backgrounds of varying chromaticity (e.g., [4]). The rationale is as follows: if the observer assumes that the background chromaticity equals the illumination chromaticity, by measuring the color appearance of the central stimulus on different backgrounds, we can calculate the extent to which the observer is compensating for the implied illumination. This can be achieved with two widely used tasks: achromatic settings and asymmetric matching. In the first task, the observer is asked to adjust a stimulus embedded in a background to appear achromatic, that is, neutral gray, while the surround is changed between sessions. Color constancy is then quantified as the change in the observers’ setting in relation to the change in the background (as a proxy of the illumination). In asymmetric matching, the observer is asked to match two stimuli embedded in two adjacent (simultaneous matching) or successive (successive matching) backgrounds so that they appear identical. Color constancy is quantified as the relationship between the test and match chromaticity in relation to the difference in illumination.

The achromatic setting task is usually intuitive for observers, but its scope is limited as it only measures the constancy of the achromatic point. Asymmetric matches have the benefit over achromatic settings that they can be collected for many different color pairs in color space, but observers often report that matching stimuli across two different contexts is difficult. Furthermore, measuring many points in color space is time consuming, limiting the number of stimuli used.

Critically, asymmetric matches depend on instructions (for a review, see [2]): observers show higher constancy when they are instructed to match the surfaces as if they were cut from the same piece of paper than if they are just instructed to make an appearance match. This may be explained by the dual nature of color experience: we can appreciate both the stability and the variability in surface colors when the illumination changes, and the two instructions might be tapping into these two different modes of color experience.

Finally, both tasks are unnatural: the goal of color constancy in real life is not to make two stimuli to appear identical or gray but to identify surface colors robustly. These shortcomings of achromatic adjustment and asymmetric matching have received more attention recently, and methods that are less dependent on instructions and observer strategies are increasingly used.

Zaidi and colleagues [8] developed a paradigm that resembles real-life color tasks. In these experiments, observers are shown two objects in one illumination context and two other objects in an adjacent illumination context. Three of the objects have the same surface color, while one is different. The observers are asked to identify the odd-one-out object. One salient advantage of this is that color need not be mentioned, making this task possibly less sensitive to observer bias or demand characteristics. To pick the odd object out, the observer has to first decide which context contains the two stimuli that differ in surface color and then decide which of those two stimuli is different to the two in the other context. This task is potentially more intuitive for observers than the traditional methods because observers are not required to make matches across contexts, and furthermore, the paradigm allows measuring contextual effects on color appearance and color discrimination within the same trial. This paradigm has revealed that observers are good but not perfect at picking the correct object, and the pattern of errors gives important insight into the strategies used by observers.

Recently, Radonjić and colleagues developed a color selection task with a similar principle to that of Zaidi [2]. Their use of rendered stimuli affords

more flexibility in the choice of stimuli and thus more accurate measurements of color constancy. Analyzing the selection data with a variant of maximum likelihood difference scaling, Radonjić et al. showed that observers were largely color constant with complex, 3D stimuli, but quite poor with simple, 2D stimuli. They further found that color constancy in a naturalistic block-sorting task was robust to changes in scene complexity (i.e., number of surfaces in the scene) and local contrast. Finally, they showed that although task instructions – whether observers were asked to match appearance or surface reflectance – affected color constancy in both simple and complex scenes, the effects were much smaller in complex scenes, and color constancy was overall much higher. This indicates that results from simple scenes and unnatural tasks cannot necessarily be generalized to natural scenes.

Constancy and Categories

Color Categorization as a Method to Study Color Constancy

Although we can discriminate millions of colors [6], we also naturally use a small number of color names to describe object color [14]. Color categories are useful when communicating about colors with others, especially considering the physiological differences across individuals in the front end of vision [9] likely to cause differences in how specific colors are perceived. In addition to being beneficial for social communication, color categorization might support color constancy. Imagine trying to pick a ripe tomato in the supermarket. The tomatoes might all have different shades varying between orange and red, and as the illumination is unknown, you have to guess which tomatoes are truly ripe. It is probably safest to pick the tomatoes that you would call red rather than orange. This makes color categorization a useful tool for characterizing real-life color constancy.

In categorical color constancy experiments, observers are asked to name the color of each of a large number of real or rendered stimuli under different real or simulated illuminations. The

stimuli are often sampled from a collection of carefully produced surfaces, such as the chips in the Munsell collection. The reflectance characteristics of these surfaces are known, and as long as the illumination spectrum is also known, the spectral power distribution of the light reflecting off the surfaces to the observer's eyes can be easily calculated as the product of the surface spectral reflectance and the illumination power spectrum. Such chips can also be rendered on a calibrated monitor display, if more control in the display of the stimuli and the illumination are required. Categorical color constancy studies often employ one neutral illuminant as a baseline, such as the standard CIE D65 illuminant which is a neutral daylight with a color temperature of 6500 K. In addition, there are often 2–4 chromatic illuminants sampled symmetrically around the neutral illuminant either toward yellowish and bluish or toward greenish and reddish. We can then ask how stable are the color names given to each chip under the different illuminants. This can be quantified by, for instance, calculating a color naming index, which is the number of “same” classifications across all illuminants divided by the total number of illuminants. 0 indicates no categorical color constancy – all color names are different – and 1 indicates perfect categorical color constancy – all names are the same. This is a useful summary measure, but it averages over all illumination changes from neutral. If we want to compare individual illumination changes, we can calculate a similar index separately for each illumination change from neutral. Averaged over all color samples, the index provides a measure of overall color constancy for each illumination.

In addition to analyzing naming consistency, category stability can further be assessed by fitting category boundaries to the naming data and analyzing the transformations in the boundaries caused by illumination changes. This is a more continuous measure of category stability that allows for analyzing how the *structure* of color naming space changes with the illumination. Finally, the centroids of each color category can be defined and their shifts analyzed. This is a measure of color constancy that can readily be

compared with the more traditional achromatic adjustment and asymmetric matching measures.

Measuring Chromatic Adaptation with Color Naming

Early investigations of color category stability characterized the effect of chromatic adaptation on color naming. Chromatic adaptation is a low-level mechanism of color constancy, whereby the visual system adapts to the overall chromaticity in the visual field, causing measurable changes in color appearance [10]. These changes can be quantified and taken as a measure of color constancy.

An early study asked observers to name a set of color stimuli spanning the visible spectrum with a small number of color names (red, green, blue, or yellow, or their combinations) under different adapting chromaticities [5]. Chromatic adaptation affected the frequency distribution of color names: under adaptation to a reddish light, the frequency of “green” increased and “red” decreased; under a bluish light, the frequency of “yellow” increased and “blue” decreased; and so forth. Functionally, this pattern is consistent with the “neutral point” of the visual system shifting toward the adapting chromaticity, making previously chromatic stimuli look achromatic (gray) and previously achromatic stimuli look tinted in the color opposite from the adapting color. The legacy of this early work lies in demonstrating that the effect of chromatic adaptation (and by extension, color constancy) can be measured with a method that is more intuitive for observers and allows for measuring the stability of more than one region of color space (also see [3]).

Although the early chromatic adaptation studies were influential, the relationship to color constancy in real life is tenuous because of how the stimuli were defined: as points in wavelength or cone contrast space and not as surfaces. That chromatic adaptation has an effect on how these kinds of stimuli are categorized indicates that the visual system is adapting to the illumination in a way that would produce partial color constancy, but there is no obvious way to determine an upper bound for adaptation, or “perfect” constancy. If the stimuli were defined in terms of identities, for

example, by their surface reflectance, constancy could be characterized as the consistency in classifying a surface in the same color category under each of the test illuminations, as explained above. In addition to measuring the effect of illumination on color naming, one could also calculate within-observer and across-observer color naming reliability for the baseline illumination.

Color Naming with Real or Simulated Surfaces

More recently, studies into categorical color constancy have used either real or simulated color samples. Troost and de Weert [13] used a large set of stimuli varying in hue, saturation, and lightness simulated under a neutral and 4 chromatic illuminations and asked observers to categorize each stimulus into 1 of 12 predetermined categories (roughly corresponding to the basic color terms). They quantified categorical color constancy in two principal ways: first, they calculated a consistency index across the five illuminations; second, they calculated the constancy of the centroids of each color category under each illumination change from neutral. They found, on average, high naming consistency and relatively high constancy from the centroids. They also ran an asymmetric matching experiment with two sets of instructions: observers were asked to either make a paper match or an appearance match. Categorical color constancy was more comparable to paper matches than to appearance matches, which is consistent with the notion that color categorization pertains to object properties rather than to “proximal” stimulus properties. Speigle and Brainard [12] also compared asymmetric matching and color naming as measures of color constancy with a systematic analysis whereby they predicted the color naming data from the matching data. They found that the agreement between matching and naming data for a given observer was comparable to the agreement between two observers for color naming. Smithson and Zaidi [11] used opponent color classification (similar to that used in [3]) to study different hypotheses about color constancy mechanisms: adaptation to the local mean, adaptation to the global mean, and temporal integration. They found that color constancy was nearly perfect

under illumination changes from a bluish to a yellowish daylight; that constancy was not determined by the global mean over the scene; and that observers were able to extract information about the illumination through spatially local temporal integration.

One distinct benefit of quantifying color constancy with color categorization is that it allows researchers to assess the stability of different regions of color space under illumination changes and to compare this to category stability across different observers to gain insight into the communicative aspects of color constancy. Olkkonen, Witzel, Hansen, and Gegenfurtner [7] had observers sort Munsell chips into different basic color categories under one neutral and four chromatic illuminations. They evaluated category sorting consistency across repetitions for the same illumination (within-observer), across different illuminations for the same observer (across-illumination), and across different observers for the same illumination (across-observer). They showed that categorical color constancy was virtually as high as within-observer consistency; in other words, an illumination change did not cause any more variability in color naming than just doing the sorting task twice under a neutral illumination. Moreover, the same color samples remained stable under an illumination change for a given observer and across-observers for the neutral illumination. This provides evidence for the notion that color naming consistency across speakers of a given language is linked to the perceptual stability of color categories under illumination changes.

Summary and Outlook

In summary, categorical color constancy has been found to be better than so-called appearance constancy, in line with the intuition that color names remain more stable than color appearance under illumination changes. Although much has been learned about both appearance constancy and category constancy in the laboratory, important open questions remain, to which color categorization might provide further insight. Do results obtained

in the laboratory hold in naturalistic viewing situations? Does color constancy depend on other object properties such as shape and material? Which visual cues are used in complex scenes to estimate surface color? An important endeavor is to formulate a computational framework in which existing results can be integrated and from which new predictions may be derived and tested. Bayesian models show much promise [1], but other frameworks are plausible. Fortunately, the methods employed to characterize color constancy are moving toward more naturalistic paradigms, which are more likely than traditional approaches to reveal real-world color constancy mechanisms. For now, researchers are limited to using either calibrated displays or real scenes, both of which have their own issues. One promising avenue is using virtual reality to combine the advantages of controllable displays and realistic scenes, once the characterization and calibration of VR devices for color display have matured.

Chromatic contrast

Definition

Color contrast describes the perceptual effects of colors' adjacency in contexts, whether they occur and are observed in two- or three-dimensional space. It is the relationship between the color of a stimulus and that of its immediate surround.

Overview

The concept of color contrast is concerned with the perception of color itself and is based upon the idea that the eye – the visual system – evaluates, a function of thinking. Light and color are therefore not merely surface phenomena but are intrinsic to human vision, to sight and insight. Light and color contrasts are primary attributes of vision. They signal the reactive eye to initiate and activate the complex visual system to respond to the visual world.

Fundamentally, the perceptions of the visual world, in its enormous diversity – the environment, man-made, or natural; people; places; animals; and vegetal life space itself – are distinguished and contextualized by the glorious capacity to *see*. The primary function of the visual system evolved to react to this diversity of features as complex contrasts of shapes and colors. These formal attributes originate and are embodied in the response of the human eye to gradients of light and its absence, shadow. Gibson links the concept of gradient to both formal and spatial effects, as well as other incremental changes [1]. In the context of color contrast, it is possible to use this concept to express increments of light and color. It is possible to think of this as a “quantification without number.” Color originates in the environment and in the visual system, as a complex and selective response to light.

Visual artists, as abstract or figurative painters, are experts in defining the images they create on two-dimensional surfaces by analyzing and expressing them as shapes and areas of light and color. All visual languages require this ability. Figurative painting depends upon the narrative orchestration of these components; for abstract works of art, shapes and colors, with their strong

associative attributes, suffice as expressive forms. Now, how does the visual system make sense in the first place of the complexity of the visual world? By responding to its gradients of light and colors as areas of contrast (Fig. 1).

But color, as Josef Albers asserted, is the most changeable component in art. And the painter Delacroix boasted he could turn a mud color into gold. It is all a matter of context. Chevreul, the chemist, in the nineteenth century defined “simultaneous contrast” as the influence of colors in backgrounds to affect the appearance of colors within their boundaries [2]. Thus, for example, a

middle gray against a black background looks light, while that same gray against a light background appears dark. Lights and darks are particularly susceptible to change (Figs. 2 and 3).

Josef Albers, in the twentieth century, explored and exhaustively expanded the simultaneous contrast law, as well as the Bezold effect, the Liebmann effect, Fechner’s psychophysical laws, and Goethe’s perceptual concepts, by his and his students’ experiments and in his great work, *The Interaction of Color* [3]. In it, the empirical studies which entailed figure–ground relationships were explored far beyond Chevreul’s. To the

appears as two

Color Contrast,**Fig. 3** Scales of gray

extent that contrasts between color complements, like a yellow and a violet, against opposing backgrounds, could appear to be similar (Figs. 4, 5, 6, and 7).

Underlying Albers' discoveries is the function of the visual system – the afterimage. The stimulus of a bright red area, after 30–60 s of exposure to the eye, will appear bright green. Just as staring at the bright light of a window in a darkened room appears as a dark window, when the eyes are diverted or shut. Another was the contrast boundary, the thin line at the edge of a color figure which appears against a contrasting background, initiating the reaction of a color change. Application of gradients of colors as linear planes can cause mixtures between adjacent color boundaries to appear as an additive third, i.e., a combined effect which regenerates the appearance of light. Changing the quantity of this gradient between two colors in a painting can cause many additive mixtures to be created. The work of Julian Stanczak and Richard Anuskiewicz, former graduate students of Albers, explore these phenomena and created the movement of Op Art in the 1960s in the USA (Fig. 8). The researchers Leo Hurvich and Dorothea Jameson describe this phenomenon in their article “From contrast to assimilation; in art and in the eye” [4] and attribute it to an

opponent response system in human vision, beginning at the retina. They are proponents of the theories of Ewald Hering, whose book *Outlines of a Theory of the Light Sense* they translated into English [5].

Swirnoff's experimental work with color began with a question: What happens to color interactions lifted from the two-dimensional plane when they interact in space? Will contrast boundaries prevail in adjacent colors when they appear as sequences of planes in space, as they do on the 2D surface? Do the size and/or placement of volumes appear different when their surfaces reflect contrasting hues? How are clues to size and distance influenced by color? What is the influence of reds (long wavelength) to blues (short wavelengths) on the appearance of volumes in space?

Beginning with Gestalt principles of form and organization, size and placement, proximity, clustering, and grouping, Swirnoff applied primary surface colors (Color-Aid) to cubes or floating planes, differing in size and placement in a space frame, and observed their effects through a series of experiments. These findings are the subject of the paper titled “Spatial Aspects of Color,” a thesis written for her Master of Fine Arts at Yale University in 1956.

Color Contrast,**Fig. 4** Reverse ground:
each X is the same color

Since then, Swirnoff's experiments with her students of design, over more than three decades, have explored contrast effects spatially, from tabletop experiments to collaborations of environmental scale, published in her book *Dimensional Color* [6]. These experiments have resulted in the assertion that color can be defined as a nonlinear dimension.

A new phenomenon was discovered: color stereopsis (Figs. 9, 10, 11, 12, 13, and 14). This occurs when three interrelated colors, separated sequentially in a space/frame, are observed

frontally through a square opening. In this study, the contrast boundary between an intermediary color, seen as adjacent to two, one placed behind, the other in front, disappears. With the absence of the middle intermediary, the visual system prefers to see the two color planes, which are frontally aligned in the space frame, appear to rotate to a diagonal position, and as they appear to intersect, trigger a strong stereoptic effect, analogous to the experience of depth when two flat images of the same subject, seen through a "stereopticon" – differing slightly in their position – fuse.

Color Contrast,
Fig. 5 Reverse
 ground: disc

Color Contrast,
Fig. 6 Three colors appear
 as two

In a problem devised to test the degree of light and shadow that defines a square pyramid, models were placed against the walls of the teaching studio to observe the patterns of light and shadow which reflect from the four white triangles of its faces (Figs. 15 and 16). The challenge – to see what degrees of contrast produced the visual effect of a pyramid – entailed placing gray papers ranging from white to black against the model in reversed order, to cancel the pattern of light and dark, causing it to appear flat, without altitude. It was found that the degree of change in the contrast values perceived, with scales of gray papers,

between white to black was *geometric* – far greater than anticipated. Once found, the contrasting grays, applied to the four triangles in opposed order to their original appearance, matched. The contrast boundaries disappeared, and the model took the appearance of a flattened surface, a bisected figure or a pyramid of increased altitude, when rotated against the wall or in the hand. Thus, the response of the visual system to contrasts of light and dark depends upon *ratios* rather than measurable reflectances.

With a grant from the IIDA, Swirnoff was able to conduct a room-sized experiment, with students

Color Contrast,

Fig. 7 Complementary colors violet and yellow appear equal

Color Contrast, Fig. 8 Julian Stanczak: *Blue Squeeze*, acrylic on canvas

in the lighting studio of Parson's School of Design in New York. The issue was to test the effect of colored light, projected on interior surfaces. The

room's interior was constructed of four nine-foot squares, three comprised the walls – two lateral ones were connected by 90° to the third back wall – all three joined to the fourth square as the floor, an open cube. Using theatrical gels, colored light was projected onto these surfaces, and it was observed how they affected the spatial appearance of the room (Figs. 17 and 18).

Color generated by light greatly intensifies and enhances the experience of color contrasts. Both ends of the visual spectrum were tried (long wave, reds and yellows, then short wave, blues) sequentially, in separate experiments, and the differences in spatial experience by the contrasts each presented, as anticipated, were obvious. The “red room,” however, provided more phenomena [6].

Against the back wall adjacent to the lateral wall planes, illuminated with red, a neutralized yellow light was projected, to fill its square surface. At the 90° juncture color contrasts intensified; when observed over time, a neutralized yellow light was seen, reflected from the back wall, adjacent to the red lateral wall, change at their mutual boundaries, at first to a green edge and then followed by the green filling in the entire square! While the adjacent red wall increasingly appeared warmer, and at the contrast boundary, the 90° juncture with the green began to reflect a yellowish light.

Color Contrast,

Fig. 9 Color stereopsis:
three colors fuse as two,
red/green

C

Color Contrast,

Fig. 10 Diagram: their
spatial appearance

These changes were observed as they occurred over a period of about 8–10 min, when surprisingly, the green at its contrast boundary with the yellowing red changed to blue/violet.

There had been a complete change in the colors of the contrast boundaries, beginning originally as a yellow-projected light, which changed the entire plane to green, followed by a contrast boundary appearing gradually as blue/violet, now adjacent

to the red wall, whose contrast boundary appeared yellow – a complete reversal of contrast from the original stimuli of color.

Clearly, the intensity of the colored light provided a much greater stimulus to the visual system than that of a surface color. The color of surfaces induced to change by their adjacency on two-dimensional surfaces contrasts mutually (simultaneous contrast); once perceived, they

Color Contrast,**Fig. 11** Diagram: spatial placement of three planes**Color Contrast,****Fig. 12** Color stereopsis value sequence of three reds

remain stable. This phenomenon, engendered by the intense light projected in space, seems to have extended to a sequence of perceptual changes which occurred after a much longer time – 8–10 min of observation. The experience all the observers had was *perceptual*. The effect eluded

all attempts to record it, by film or digitally. To account for these changes, elicited over a period of time, Swirnoff named the effect “sequential contrast.”

To conclude, the evidence raised by these experiments suggests that the issue of color

Color Contrast,

Fig. 13 Diagram: their spatial appearance

Color Contrast,

Fig. 14 Diagram: alternative appearance as zigzag

contrast is fundamental to and an essential part of the process of sight. Far beyond the purview of design science to explain, however, they offer a challenge now to neurology and brain science.

Effects in Perception

Contrast detection is the basic visual task from which all other visual behaviors are derived. The human visual system gives virtually no useful information unless there is a contrast in the retina

Color Contrast,

Fig. 15 Pyramids: *left*, the white model; *right*, model flattened by grays

Color Contrast, Fig. 16 Pyramid rotated 90° appears bisected

(thus, also in the environment that is being viewed). A small object, or a patch, can only be seen on a larger one if the two differ in color. These differences are known as contrast [7].

Sensation of color, or interpretation of color in the brain, is not only affected by adjacent areas of the stimulus, but also by the light under which the stimulus is seen. Two examples of this are the Helson-Judd effect and the Bezold-Brücke hue shift. The Helson-Judd effect is the tendency of lighter achromatic surfaces to take on the hue of the illuminant under which they are viewed and

darkers achromatic surfaces to take on the complementary hue. The Bezold-Brücke hue shift is a shift in the apparent color of a stimulus toward yellow or blue with the increasing intensity of light. If a pair of long-wavelength lights differing only in intensity is compared, the higher intensity stimulus will look more yellow and less red than the lower intensity light. For shorter wavelengths, higher-intensity lights look more blue and less green than lower-intensity lights [7].

Contrast perception also causes visual effects that lead to variance in color sensation. This may be caused by either the psychophysics of the eye or by the interpretation of the brain. These effects are: successive contrast, simultaneous contrast, edge contrast, and assimilation (reversed contrast).

Successive contrast is the visual effect which occurs when eyes are fixed on a colored patch for a sufficient period of time and then moved on to another patch of a different color. It is likely that the image of the first patch will be perceived upon the image of the second with its afterimage [7]. An afterimage is the visual effect that occurs after light stimulus has been removed. In the case of successive contrast, afterimage complementary color of the initially viewed image will be imposed on the lately viewed image.

Simultaneous contrast is the visual effect which occurs when two different color patches are viewed together, where both will exhibit

Color Contrast,**Fig. 17** The room illuminated by LED**Color Contrast, Fig. 18** The room's back wall changing to green

changes of appearance. Simultaneous contrast is affected by the distance between two colors. If two different color patches of equal size are placed side by side, both will exhibit changes in color appearance. When the patches are separated, the changes decrease and eventually diminish, as the distance between them is increased. Simultaneous contrast effects the hue changes by roughly superimposing the complementary color of the background on the foreground patch. This hue change is accompanied by changes in the perceived saturation depending on the afterimage complementary color produced. For example, if a blue-green

patch is viewed against a red background, the patch will be perceived as blue-green again (the afterimage of red being a blue-green), but with an increased saturation [8].

If two areas of uniform colors having the same hue but slightly different luminance factor are viewed, adjacent to the boundary between the two areas, there is a relative enhancement of lightness of the lighter area and a corresponding darkening of the adjoining area [8]. This is called edge contrast. If a black line is drawn along the edge at which two areas join, the effect of edge contrast is lost. The edge contrast phenomenon is caused psychophysically by interactions among nerve cells in the retina. It is also referred to as the Mach band effect, the Mach contrast (named after the physicist Ernst Mach), or the border contrast [7].

Assimilation (reversed contrast) is the visual effect which occurs when two distinctly perceived colors seem to shift in appearance toward each other. An example would be strips of colors, namely, red, yellow, and blue. The red strips on the yellow background appear yellowish, and on the blue background, the same red strips appear bluish. Assimilation is also known as the Bezold spreading effect. Assimilation should not be confused with simultaneous contrast. In simultaneous contrast, a red area surrounded by a yellow area

would tend to look more bluish (not yellowish); surrounded by a blue area, it would tend to look more yellowish (not bluish) [8]. It is also important to introduce a relation between the viewing distance and the effect that will be perceived. As the viewing distance is increased, producing retinal images of finer detail would be more possible, and a transition from simultaneous contrast to assimilation will occur. Finally, when a distance is reached beyond which the pattern is distinguishable, the visual experience of pointillism takes over where colors put on a surface will be perceived as a spatial mixture (optical mixture) [7].

Sonia Delaunay's Simultaneous Contrast

This concluding section focuses on Sonia Delaunay's and the early modernism's application of simultaneous contrast. For Sonia, and also for Robert Delaunay, and the poets Apollinaire and Cendrars, simultaneous contrast was a tool used to express the new era's speed, velocity, and movement. In Paris, the Russian-French artist Sonia Delaunay (1885–1979) worked with strong contrasts of color in her early expressionist painting period around 1906. A few years later, she started to work with simultaneous contrast in a nonfigurative way in several projects: paintings, fashion, ballet costumes, textiles, prints, books, and interior designs. As early as 1912, she created one of the first painting techniques in an abstract form with colors applied to large areas with the aim of achieving an interaction of color contrast [9]. She picked up the concept of simultaneous contrast from Chevreul and called her style of painting *simultanée*. Principally, she worked with color contrast to add power and chromatic strength to the tints.

Sonia – and her husband, the painter Robert Delaunay – first observed Chevreul's law in nature. In Spain and Portugal, she writes: the diffusion of light is the purest. The light is so strong that the colors themselves become distinct and their hues become robust. No haze or tones of gray interfere and mix the colors; no achromatic

grayed effects appear. The quality of this light allowed the artists “to go even further than Chevreul in finding dissonances in colored light” [10]. She explains “dissonances” as “rapid vibrations, which provoked greater color exaltation by the juxtaposition of specific hot and cold colors” [10]. To create the color vibrations, the Delaunays began to divide the shades of colors into hot and cold. This meant working with complementary colors and, to an even greater degree, with *cold* and *warm* color contrasts. Sonia Delaunay states that colors “agitated by hot and cold dissonances provoke a stimulating response” to the viewer [10].

Simultaneous Contrasts in Patterns

Sonia Delaunay's patterns in pure colors and in new color relationships are varied and have abstract forms: arcs and circles, rectangles, and triangles. For her, the circle was a symbol of the sun and also of simultaneous action. Her patterns change in rhythmic movements corresponding to their movements in value (lightness) and hue. Dresses and costumes are also inspired by the natural movement of the body. She began from the four basic colors – red, yellow, green, and blue – and from black and white. The red hue is often mixed with yellow to form an orange-red. The green is mixed with yellow to form a hue similar to the color of a mimosa flower. The blue is a medium blue, and the yellow is strong. In addition, she uses gray [11].

Around 1912, standard fabrics usually had large flowers against black or strongly colored backgrounds [9]. Sonia Delaunay's simultaneous fabrics changed this custom; she manufactured the same elements as those used in her paintings. Her abstract patterns are simple and have clear motifs in composition and color (quite similar to some African patterns). The colors are often vivid, but they harmonize most agreeably. Characteristic of her textile design is that the forms and patterns may well appear geometric, but the color surfaces are “characterized by *rhythm*” [10]. Due to Sonia Delaunay's simultaneous placement of the colors,

they produce new and original effects “right before your eyes” [10]. They are thus responsive to the architecture of modern life, to the new active way of living. In connection with this textile creation, she began to work with the first “simultaneous automobile,” a *Citroën B12* (1925), painted in the colors of the rainbow. In this way, she was at the forefront in the showing of art outside of the salons.

Simultaneous Contrast in Costume and in Fashion

During the summer of 1913, Sonia Delaunay began to design simultaneous dresses. She made and mounted them in collages made of textile. These dresses caught a new wave in fashion corresponding with the latest popular dances of the time, foxtrot and tango. In her abstract forms of arcs, circles, rectangles, and triangles, she created a movement of color. But the forms and the contrasting colors also enhanced the natural movement of the forms of the body, matching with the rhythms of Latin music. In the dancehall the Bal Bullier in Montparnasse, one could see the action of the dancers united with the action of color and light. Sonia Delaunay was commissioned to design the costume for the ballet *Cléopâtre* (1918). Working for the theater, she could experiment with successive designs for lengths of fabric: textiles wrapped around the human form, the body set into action in dance, all visual movements of the costume. Cleopatra’s costume was built up of discs in pure colors decorated with sequins and pearls. The ballet established Sonia Delaunay’s name as an innovator in both costume and fashion [12]. In 1922, a textile manufacturer in Lyon, France, asked her for a set of fabric designs and promptly ordered 50 designs for silk. For the commission, she began to study color relations and introduced abstract geometrical designs in printed silk. The subject of textile studies refined her control of the interaction of colors [11]. A few years later, on Boulevard Malesherbes in Paris 1925, Sonia Delaunay opened her own shop, the *Boutique Simultanée*.

There she offered simultaneous design in the form of coats, dresses, handbags, and even interior furnishings.

Changes in sensitivity or appearance in response
to spatial or temporal variations in color

Concepts

All sensory systems continuously adjust sensitivity or adapt to match their responses to the current stimulus context. In vision, these adjustments occur at many levels along the visual pathway and adjust to most if not all of the properties encoded by the visual system, from simple image features to high-level representations like the attributes of a face [1]. Thus adaptation to color is a specific example of a very general and ubiquitous process affecting everything we see.

Most studies of color or “chromatic adaptation” have focused on the changes in sensitivity and perception resulting from exposure to a change in the average color of the stimulus [2]. Chromatic adaptation begins as early as the photoreceptors, which like a camera must adjust their limited response range so that it is centered on the current light level. Since the different cone classes are each light adapting independently, a light that differentially stimulates the cones will lead to a change in the relative sensitivity to different spectra. For example, a longwave (reddish) spectrum is a strong stimulus for the L cones while

a weak stimulus for the S cones. Thus in the presence of this light the L-cone sensitivity will be reduced while the S-cone sensitivity will be increased. Sensitivity changes that occur independently in the cones and vary inversely with the light level are known as von Kries adaptation. Adjustments of this kind tend to renormalize color percepts so that the cone signals are equated for the current spectrum. Thus after adapting to the longwave spectrum the responses in the L and S cones will become more similar and the initially red light will appear more gray. In turn, a light that appeared gray before the adaptation will appear bluish after adapting, as a negative afterimage of the red adapting color. This chromatic adaptation is thought to play an important role in color constancy, by adjusting sensitivity to discount changes in the color of objects resulting from changes in the illumination [3].

However, in addition to the mean, color vision also adapts to the range or variance of the color distribution. These adjustments are known as contrast adaptation [2]. Contrast adaptation is again a very general process and has been very widely studied in the case of spatial vision, where it is the range of luminance levels that is typically varied [4]. For example, exposure to a high contrast grating (alternate light and dark bars) results in a loss in contrast sensitivity. The threshold contrast difference for detecting the grating increases, while the apparent contrast of visible gratings decreases. These effects are selective for the spatial properties of the grating. That is, sensitivity is reduced for patterns that have a similar size (spatial frequency) or orientation as the adapting grating, while little affected for spatially distinct patterns. This also again leads to negative aftereffects in the appearance of other patterns. After adapting to a tilted grating, a vertical grating appears tilted in the opposite direction (the tilt aftereffect) and the perceived size or spatial frequency of gratings appears biased away from the adapting grating. Like the example above of the cones, these results are again consistent with gain changes in different mechanisms or visual “channels” sensitive to different spatial properties of the stimulus, each adjusting according to the level at which they are stimulated. Indeed, measurements

of the selectivity of the aftereffects of contrast adaptation were a primary tool in the study of spatial and temporal vision and in the development of channel models of visual coding [4]. For this reason, adaptation has often been described as “the psychologist’s electrode.” However, it should be noted that the aftereffects also depend on the network properties and interactions within the system and thus not simply on how each mechanism adapts in isolation [5].

History

Contrast adaptation in the context of color vision has received much less attention, and there are far fewer studies compared to chromatic (mean) adaptation. It is nevertheless an important and robust phenomenon with important functional implications. While some earlier studies examined adaptation to temporal color contrast (flicker), a study by Krauskopf, Williams, and Heeley [6] was seminal in exploiting color contrast adaptation to examine the color selectivity of the aftereffects. Their stimulus was a sinusoidal modulation of the color or luminance of a uniform field along different directions in color space. All had the same mean and thus produced the same state of chromatic adaptation. However the flicker reduced sensitivity to detecting a color change (an effect they called habituation), and these effects were again selective for the color of the adapting stimulus. For example, adapting to reddish-greenish flicker made it harder to detect these colors than other colors. These aftereffects could not be accounted for by response changes in the receptors, and instead pointed to desensitization in postreceptoral mechanisms that drew on different combinations of the cone signals. For instance, adapting to achromatic flicker strongly modulates the signals in all of the cones. This reduced sensitivity to luminance variations (in mechanisms that sum the cone inputs), but had little effect on chromatic variations (which are instead detected by mechanisms sensitive to the differences between the cone signals). The

pattern of selectivity revealed three primary adaptable mechanisms tuned to achromatic stimuli or to chromatic stimuli that varied the excitation of the L vs. M cones or the S cones versus the L and M cones. These were thus identified as the “cardinal directions” of color space and were subsequently shown to correspond to the color tuning of the primary pathways carrying information from the retina to the cortex [7]. The cardinal axes have since become a standard metric for designing and interpreting experiments in color vision, impacting thousands of studies. It is therefore noteworthy that it was through color contrast adaptation that they were first firmly established, though again surprisingly few studies have followed up on the properties and consequences of this adaptation.

Further analyses by Krauskopf and colleagues showed that there was also some selectivity of the adaptation for chromatic directions intermediate to the cardinal axes [8]. This finding established the presence of additional “higher order color mechanisms,” which have also strongly influenced modern approaches and theories about human color vision. Subsequently Webster and Mollon [9] explored how the adaptation to temporal color contrast affected color appearance. The adaptation produced large and selective changes in both saturation and hue. Specifically, adapting to a given axis in color space (e.g., a modulation along the LvsM cardinal axis) reduced perceived contrast (saturation) the most along the adapting axis, and biased the perceived hue of other chromatic directions away from the adapting axis and toward an orthogonal direction in color space (Fig. 1a). For example, the LvsM adaptation caused a previously pure blue or yellow hue to appear less like the LvsM (reddish-cyan) axis and more like the hues (purple or lime) of the S cardinal axis. Both the saturation and hue changes are consistent with a loss of sensitivity in the mechanisms tuned to the adapting mechanisms, though there is also evidence for a dissociation, since at high test contrasts, colors can exhibit a large hue bias despite small changes in their perceived contrast.

Color Contrast Adaptation, Fig. 1 (a) Effects of contrast adaptation on color appearance. The outer circle depicts a set of test stimuli with equal contrast but spanning different angles within the LvsM and SvsLM plane.

Key Principles

The adaptation-induced biases in hue are similar to spatial orientation aftereffects, but reflect tilt aftereffects in the perceived direction (hue) within color space. As with spatial orientation, the changes in color appearance from contrast adaptation can be selective for any arbitrary color direction, again implicating multiple mechanisms tuned to different directions in color space. However, unlike the tilt aftereffect, which at best produces a subtle bias in perceived orientation (about 2 deg), the biases in hue can be dramatic and up to 30 deg. or more. This difference is consistent with a broader tuning for hue mechanisms compared to orientation channels, at least at the level at which the adaptation is occurring. The common effects of adaptation across different stimulus dimensions point to common coding principles underlying the representations for different visual attributes [1, 4]. In particular, they suggest that the kinds of multiple-channel population codes that are widely assumed for form and motion perception also underlie the representation of color appearance (Fig. 1b). The representation implied by contrast adaptation is thus very different from the traditional two-channel (red vs. green and blue vs. yellow) model of opponent color theory, but is consistent with a wealth of behavioral and physiological evidence for multiple higher order color mechanisms.

In contrast to chromatic adaptation, the primary sites of the sensitivity changes in color and spatial contrast adaptation are thought to be cortical. This is suggested by the fact that the color aftereffects are also selective for spatial properties of the stimulus like orientation and that the adaptation shows some interocular transfer, properties that the neurons first become selective for in primary visual cortex. Cells earlier in the visual pathway show weak adaptation to chromatic

contrast, though the degree of adaptation observed depends on the approach to measure it. Neural correlates of contrast adaptation have also been found in the response changes in single cells or in the brain activity (BOLD responses) measured by fMRI. However, the actual relationships between different neural and perceptual measurements of contrast adaptation are complex and uncertain.

Thus in terms of their properties, chromatic adaptation and contrast adaptation reflect adjustments to two different statistics of the stimulus (the mean and the variance) arising at two different stages of the visual system (retinal and cortical) [2]. Consistent with this, the two types of adaptation produce separable effects on sensitivity and appearance (Fig. 2). Both types of adaptation also have a spatial analog. Just as a uniform color surround alters the hue of a central field (simultaneous color contrast), surrounding a field with a high-contrast background alters the perceived contrast, an effect which once more reflects very general processes of contrast normalization in sensory systems [10].

Phenomena

Both types of adaptation are important in natural viewing [1]. For example, the perceived contrast or colorfulness of natural or artificial images depends on the contrasts of the images that observers are adapted to. Color contrast in natural scenes is not random and instead tends to have a strong blue-yellow bias in part because of the dominant colors of earth and sky. The visual system is thus naturally exposed to stronger blue-yellow contrasts. Adaptation to this predicts the consistent finding that observers tend to be less sensitive to blue-yellow stimuli compared to other chromatic directions. These sensitivity

Color Contrast Adaptation, Fig. 1 (continued) Adaptation to the LvsM axis (arrows) selectively reduces sensitivity to the LvsM component of each test stimulus. This reduces perceived contrast (saturation) and also rotates the perceived hue angle away from the adapting axis. (b) Both

the contrast and hue changes are consistent with response changes in multiple mechanisms tuned to different axes in the chromatic plane. Adaptation to the LvsM axis (arrows) reduces the responses in mechanisms sensitive to this axis, thus biasing the distribution of responses across the channels

Color Contrast Adaptation, Fig. 2 Combined effects of chromatic adaptation and color contrast adaptation. “Pre” shows a set of colors centered on a yellowish mean (DC) chromaticity, while “post” plot the perceived colors after adaptation. Chromatic adaptation adjusts to the DC color so that it appears gray and shifts the set of colors so

that they appear centered on the origin (DC only). If observers are adapted to the same mean DC chromaticity but contrast is varied along the LvsM axis (AC,) then in addition to the mean color change there is a loss in perceived contrast along the LvsM axis (DC + AC)

differences are also evident in most uniform color spaces, which attempt to scale stimuli so that equal perceptual differences correspond to equal distances within the space. In these spaces the differences in cone signals are larger along the blue–yellow quadrant, implying weaker visual sensitivity. Ecosystems also vary systematically in their color contrasts and this suggests that individuals exposed to different environments (e.g., a forest or desert) may be held in different states of contrast adaptation. Moreover, contrast adaptation is also likely to be a factor in how the visual system adapts to the unnatural environments than humans increasingly occupy. An important case is the new generation of wide gamut lighting and displays. These increase the chromatic

contrasts that observers are exposed to, and this predicts that adaptation to this increase will consequently reduce their contrast sensitivity.

It is less well appreciated that both chromatic and contrast adaptation also adjust to variations within or between observers [1]. For example, it is in part because of these adjustments that color perception remains relatively stable as we age or as the world falls on different retinal locations [11]. The stability arises because in this case the visual system is recalibrating to match a world that itself remains stable. In the case of contrast an intriguing example is how the world might appear to a color deficient observer. Anomalous trichromats retain three kinds of cones but with only small differences in the spectral peaks of

Color Contrast Adaptation, Fig. 3 Monet's *Sunrise (Marine)*. The palette of the original left image was adapted to equate the mean and contrast to a color distribution

characteristic of natural outdoor scenes (after [14]). Digital image courtesy of Getty's Open Content Program

their two longer-wave pigments. This reduces the reddish-green contrasts signaled by these cones, yet the visual system could potentially adapt to the weakened contrast and thereby increase sensitivity so that these colors appear stronger. To mediate this stability, the mechanisms of adaptation must themselves remain stable with aging, and importantly, color contrast adaptation appears to remain robust across the adult lifespan, with potentially even larger adaptation effects in older populations.

The timescales of color contrast adaptation are not well characterized, and there is conflicting evidence as to whether or not the effect can build up with longer periods of adaptation. Strong after-effects of spatial contrast adaptation can occur with brief exposures, and at least some adjustments can occur within a few milliseconds, recalibrating perception with each eye movement. For other adjustments it is advantageous to average over longer times (e.g., to adjust to the average color or contrast of a scene rather than to each individual surface as it is fixated). There is also growing evidence for adaptation effects that unfold over hours, days or even months [12]. A classic example is the McCollough Effect, in which the color aftereffects are contingent on the spatial orientation of the adapting pattern [13]. These aftereffects may persist permanently until they are actively extinguished by adapting to

the complementary stimulus. However, it is not known how the McCollough Effect – or for that matter other types of long-term adaptation – are related to the short-term response changes measured in conventional studies of contrast adaptation.

Because the general ways that chromatic and contrast adaptation alter color perception are known in principle, it is possible to simulate how the world might look to observers adapted to different environments or different observers adapted to the same environment [14] (Fig. 3). This process of adapting the images rather than the observer also has the advantage that adaptation can be simulated for very long timescales that are impractical to study by changing the observer. Measuring visual performance for these adapted images can then reveal some of the perceptual consequences and advantages of contrast adaptation, by assessing what observers can see and do with images that have been adapted to better match their current sensitivity [15].

Function

The fact that adaptation is a hallmark property of all sensory processes suggests it confers essential advantages, and a wide variety of interrelated functions have been proposed [1]. One set derives

from information theory and emphasizes the role of adaptation in optimizing coding efficiency by matching the limited response range of neurons to the current range of stimuli. This also predicts the role of adaptation in normalizing or equating the responses across different mechanisms. This normalization is also closely related to ideas about how adaptation contributes to perceptual constancy. If the world or the observer changes, then adaptation implements a compensatory adjustment to discount the change and thus stabilize perception. A further related advantage is predictive coding, in which the sensory system adapts to remove the response to the absolute or expected stimulus level in order to preserve resources for signaling the relative differences or unexpected properties. In turn, this principle has been associated with the hypothesized effects of adaptation on heightening the perceptual salience of novel colors or spatial stimuli in the environment.

Definition

In the study of linguistics, a **corpus** is a data set of naturally occurring language (speech or writing)

that can be used to generate or test linguistic hypotheses. The study of color naming worldwide has been carried out using three types of data sets: (1) corpora of empirical color-naming data collected from native speakers of many languages; (2) scholarly data sets where the color terms are obtained from dictionaries, wordlists, and other secondary sources; and (3) philological data sets based on analysis of ancient texts.

History of Color Name Corpora and Scholarly Data Sets

In the middle of the nineteenth century, color-name data sets were primarily from philological analyses of ancient texts [1, 2]. Analyses of living languages soon followed, based on the reports of European missionaries and colonialists [3, 4]. In the twentieth century, influential data sets were elicited directly from native speakers [5], finally culminating in full-fledged empirical corpora of color terms elicited using physical color samples, reported by Paul Kay and his collaborators [6, 7]. Subsequently, scholarly data sets were published based on analyses of secondary sources [8, 9]. These data sets have been used to test specific hypotheses about the causes of variation in color naming across languages.

From the study of corpora and scholarly data sets, it has been known for over 150 years that languages differ in the number of color terms in common use. Particularly, languages differ greatly in how they name the cool colors that are called “blue” and “green” in English (Fig. 1).

Some languages, such as English, use a word *BLUE* that means only blue, in conjunction with a word *GREEN* that means only green. Other languages use a single term (here and elsewhere, “*GRUE*”) that means green or blue, and still other languages use a word (here, “*BLACK*”) that means both black and blue, to name the cool colors, in conjunction with *WHITE*, which names the light and warm colors.

Scholars in the nineteenth century established the two general explanations for this diversity of color terms across languages, which still guide much of the research on the topic today. The first explanation was that the people who spoke languages with few color terms had deficient color vision. This speculation was at first based on the philological analysis of extinct languages and arose in part because of general interest in the theory of evolution in the latter half of the nineteenth century. Proponents of this view speculated that humans and their color vision had evolved since ancient times. The second explanation was that people living at different times and in different cultures need to differentiate between different colors, so their languages have different numbers of color terms. Particularly, ancient languages lived in simpler times and consequently had fewer color terms in their lexicons.

The Color Deficiency Explanation

The earliest scholar to study this variability across languages was **William Ewart Gladstone**, prime minister of England over the latter half of the

Color Dictionaries and Corpora, Fig. 1 (a) Examples of cool colors; (b–d) false color coding of the corresponding color terms. The center sample of the

diagram is called *BLUE* by some informants and *GREEN* by others in (b), but it is called *GRUE* by all informants in (c), and it is called *BLACK* by all informants in (d)

nineteenth century and scholar of ancient Greek. Gladstone reported that Homer's epic poems used a "paucity" of color terms, mostly relating to dark and light, with a few instances of terms that may have corresponded to *YELLOW*, *RED*, *VIOLET*, and *INDIGO*, but not *GREEN* and not *BLUE* [1]. The German philologist **Lazarus Geiger** [2] reviewed evidence from even older sources: the Hindu Veda hymns of India, the Zend-Avesta books of the Parsees, and the Old Testament of the Bible, as well as ancient Greek and Roman sources. Geiger argued that color lexicons progressed over time from a *BLACK*-and-*WHITE* system to a *BLACK*-and-*RED* system (where *RED* was his term for white or warm colors), then differentiating *YELLOW*, then adding *GREEN*, then *BLUE*. "In the earliest mental productions that are preserved to us of the various peoples of the earth . . . notwithstanding a thousand obvious and often urgently pressing occasions that presented themselves, the colour blue is not mentioned at all. . . . Of the words that in any language that are used for blue, a smaller number originally signified green; the greater number in the earliest time signified black" [Ref. 2, pp. 49, 52].

Gladstone speculated that the Greek of the heroic age "had a less-evolved color sense that prevented him from seeing and distinguishing the many colors that modern people can see easily" [1] [p. 496]. Geiger came to a similar conclusion: "Were the organs of man's senses thousands of years ago in the same condition as now. . . ? [p. 60] The circumstance that the colour-terms originate according to a definite succession, and originate so everywhere, must have a common cause. This cause cannot consist in the primarily defective distinction merely. . . . [W]e must assume a gradually and regularly rising sensibility to impressions of colour."

The Cultural Explanation

Under the influence of the Darwinian thinking of the day, the English writer **Grant Allen** and the German ophthalmologist **Hugo Magnus** [23] thought that "primitive tribes" who lived in

modern times could provide information on the color naming and sensory color capabilities of ancient humans. Therefore, they sent questionnaires to Christian missionaries, explorers, and diplomats around the world, asking them about the color capabilities of the people they encountered and the color terms in their informants' native languages. Based on their responses, Allen wrote that "the colour-sense is, as a whole, absolutely identical throughout all branches of the human race" [Ref. 3, pp. 205] and afforded "a reasonable presumption in favour of a colour-sense in the earliest members of the human race." He therefore rejected the view, espoused by Gladstone and Geiger, that the reduced color vocabulary observed in many ancient and modern languages was due to a color vision defect. Magnus partly agreed, with qualification: "While some groups confirmed an awareness of colour, which rated in no way below that of the achievements of highly developed nations, others again gave proof of the lack of ability in identifying colours of middle- or short-wavelengths, and this was noted particularly in relationship to 'blue'" [Ref. 4, p. 145].

Based on the results of his surveys, Grant Allen proposed the second, cultural explanation of the diversity of color naming worldwide. "Words arise just in proportion to the necessity which exists for conveying their meaning. . . . Primitive man in his very earliest stage will have no colour terms whatsoever. . . . But when man comes to employ a pigment, the name of the pigment will easily glide into an adjectival sense. . . . [p. 259]. The further differentiation of the colour-vocabulary . . . is most developed among . . . dyers, drapers, milliners, and others who have to deal with coloured articles of clothing. . . ." "How then are we to explain the singular fact, which Mr. Gladstone undoubtedly succeeds in proving, that the Homeric ballads contain few actual colour-epithets? In the following manner, it seems to me. Language is at any time an index of the needs of intercommunication, not of the abstract perceptions, of those who use it."

Hugo Magnus became interested in the discrepancy between the excellent color awareness of many of the peoples in his survey and their

difficult color naming. His summary of how color terms co-occur in languages is reminiscent of the results of Gladstone and Geiger: "...while in some...communities the known terminology begins and ends with 'red', it stretches in other ones well beyond the 'yellow,' and with yet others, even beyond the 'green'." Magnus began his research under the influence of Gladstone and Geiger, but in the end he was also influenced by Grant Allen's work. Magnus concluded, "one might be tempted to formulate a... natural law of awareness – be that linguistically engendered or physiologically-anatomically conditioned as part of the natural growth of man."

Empirical Studies

The empirical tradition in the study of color terminology began with **W. H. R. Rivers**, a medical doctor and anthropologist, who traveled as an explorer to several parts of the world on behalf of the Royal Anthropological Institute. In his book *Reports of the Cambridge Anthropological Expedition to Torres Straits* [5], he compared the color vocabularies of three languages spoken by the Kiwai, Murray Islanders, and Western Tribes of the Torres Straits. "...As regards blue, the three languages may be taken as representatives of three stages in the evolution of a nomenclature for this colour. In Kiwai there is no word for blue; may blues are called names which mean black. ... while other blues are called by the same word which is used for green. In Murray Island there is no proper native term used for blue. Some of the natives, especially the older men, use [a native term], which means black, but the great majority use a term borrowed from English. ... The language of the Western Tribe of Torres Straits presents a more developed stage. ... [a native term] ... is used definitely for blue, but is also used for green. ... however, traces of the tendency to confuse blue and black still persist. ..." Rivers also reviewed scholarly evidence from ancient and contemporary sources, including his own work in Egypt and the Andaman Islands. All the empirical evidence he reviewed supported his view that the naming of blue is highly variable across

cultures: some call blue things *BLACK*, some call them *GREEN*, and some call them with a particular word for *BLUE*. He believed that *BLACK* was the most ancient term, *GREEN* was used in more developed societies, and *BLUE* was the most advanced color term.

In the twentieth century, the large-scale study of color naming across many languages was dormant until 1969, when **Brent Berlin** and **Paul Kay** published their monograph *Basic Color Terms: Their Universality and Evolution* [6]. Berlin and Kay collected a corpus of empirical color-naming data on 20 languages on individual speakers who lived in the San Francisco Bay area in the mid-1960s. They showed each subject an array of Munsell color samples and asked them to indicate the range of colors they assigned to each color term in his or her native language. Berlin and Kay augmented their corpus with scholarly data on the color lexicons of 78 additional languages, which were obtained from dictionaries and other scholarly sources. Berlin and Kay observed that all the color terms in all the color lexicons in their data set were drawn on a superset of only 11 universal **basic color terms**: *BLACK*, *WHITE*, *RED*, *YELLOW*, *GREEN*, *BLUE*, *BROWN*, *ORANGE*, *PINK*, *PURPLE*, and *GRAY*. They also observed that these color terms occurred together in only about seven different combinations. They speculated that these seven combinations of basic color terms represented seven ordered **stages** along an **evolutionary sequence** whereby the most primitive languages distinguish only *BLACK* and *WHITE*, and other color terms are added in a fixed sequence, until all 11 color terms are present. Berlin and Kay assigned each language in their data set to one of their seven stages of color term evolution. Their idea about the evolution of color terms was in line with the ideas advanced by Gladstone, Geiger, Allen, Magnus, and Rivers, although their explanation for the evolution of color terms was more in line with Allen's.

The methodology of Berlin and Kay and their theoretical interpretation of their data were criticized by others [e.g., Ref. 10]. Therefore, in the 1970s, Kay, Berlin, and their colleagues collected a new corpus of data on 110 world languages: the

World Color Survey. The languages in the World Color Survey (WCS) were mostly unwritten and were spoken in traditional societies with limited contact with Western industrialized culture. The geographical distribution of the WCS languages was generally quite similar to the worldwide distribution of all living languages (www.ethnologue.com/show_map.asp?name=World&seq=10). The WCS data set was made up of empirical color-naming data provided in face-to-face interviews by about 24 speakers of each language. Each subject viewed 330 color samples, one at a time, and provided the color term they used in everyday life. Kay, Berlin, Maffi, Merrifield, and Cook published the *World Color Survey* [7], a book-length analysis of this corpus in which they identified each color term in each language with 1 of the 11 basic color terms of Berlin and Kay and updated their theory of color term evolution. They assigned each language to one of five stages, with two stages having three versions each, in their revised theory.

The **World Color Survey** corpus of color terms is available online and has been analyzed by Paul Kay and his colleagues [11, 12], who found evidence of universal color categories across the WCS languages. Independently, Lindsey and Brown [13] performed a cluster analysis of the color-naming patterns in the WCS corpus and discovered about eight distinct clusters of chromatic color terms, which, with the addition of the three achromatic terms *BLACK*, *WHITE*, and *GRAY*, corresponded approximately to the 11 basic color terms of Berlin and Kay. They further found that these color terms fell into about four color-naming systems (“motifs”) [14], which corresponded only loosely to the seven stages of Berlin and Kay or the five stages of the WCS. Similarly to all previous scholars and investigators, Lindsey and Brown found that the motifs differed most prominently in the color terms used to name cool colors that speakers of English call “blue.” In correspondence with the four motifs, some informants called blue samples *DARK*, some called them *GRUE*, some called them *BLUE*, and a few individuals called blue samples *GRAY* (a color term that was also used for middle-value neutral samples). Almost every World Color

Survey language revealed individual differences among its speakers, and at least three of the four motifs were represented among the speakers of most languages [see also Ref. 15]. Previous empirical and scholarly work that sought the color terms in each language as a whole, including the data sets in Fig. 2, could not reveal this prominent variation among individuals.

In the tradition of Allen, Kay and his colleagues [e.g., Ref. 16] argued that larger color lexicons, at a later stage along their evolutionary sequence, occur in technologically advanced, economically developed cultures, where the presence of colored artifacts and trade with other cultures requires a larger, more nuanced color vocabulary. Several authors [17, 18] have examined this hypothesis by comparing the number of terms that Berlin and Kay ascribed to each language to its level of development as published by [19].

Modern investigators have examined this diversity across languages in the naming of blue, which was common to the analyses of Gladstone, Geiger, Magnus, Berlin and Kay, and the WCS. Marc H. Bornstein [8] assembled a set of data on the presence or absence of *BLUE* in 145 languages from published sources and showed them on a world map. His analysis revealed a pronounced latitude effect: *BLACK* and *GRUE* languages tended to be spoken near the equator, and *BLUE* languages tended to be spoken at temperate latitudes (Fig. 2). Bornstein attributed this to the possible geographical variation in intraocular pigmentation, including the amount of melanin in the eye (the pigment epithelium and the iris) and the tint of the ocular media (the lens and macular pigment). Lindsey and Brown [20] reported that the yellow tint of the ocular lens, caused by the intense UVB in equatorial sunlight, could produce changes in color-naming behavior that were similar to those observed in *GRUE* languages. However, other work suggests that a causal link between the tint of the ocular lens and the naming of colors is at least partly modified by long-term chromatic adaptation [16, 21]. Brown and Lindsey [9] performed a geographical analysis of data on 118 ethnolinguistic groups for which both red-green color deficiency data (protan and deutan defects, not related to blue) and scholarly or

Color Dictionaries and Corpora, Fig. 2 The geographical distribution of languages that use BLUE/GREEN (top), GRUE (middle), or BLACK (bottom) to name the cool colors is known to be uneven worldwide. Maps show the localities of 371 living languages from color term corpora and scholarly data sets. Circles, 20 corpus languages and 77 living languages from scholarly sources from Berlin and Kay [6]; squares, 106 additional corpus languages from the World Color Survey [7], excluding two

already included in [6] and two that could not be typed; diamonds, 75 additional scholarly sources from Bornstein [8]; triangles, 93 additional scholarly sources from Brown and Lindsey [9]. Colonial languages (e.g., English, French, Spanish) are plotted where they were spoken in 1492 CE. Assignment of languages to BLUE/GREEN, GRUE, or BLACK types was made by the authors of the original data sets

dictionary data were available, also from published sources. The geographical results of Brown and Lindsey generally agreed with the results of Bornstein.

Color Naming Worldwide

There is still no single well-accepted explanation for the differences between languages in the use of *BLUE*, *GRUE*, and *BLACK*. Does *BLUE* vary across languages because of physiological differences among people, perhaps due to their different exposure to the sun, as Bornstein and Lindsey and Brown (and Gladstone and Geiger before them) suggested? If so, there might be a correlation between *BLUE* and the physical geography of the localities where these languages are spoken. Is the variation in *BLUE* due to the superior economic and cultural development of advanced nations, as Kay and his colleagues (and Allen and Magnus before them) suggested? If so, there might be a correlation between *BLUE* and the societal characteristics of the cultures where these languages are spoken. Or, is it a historical linguistic phenomenon, with the geographical patterns in the Old World being caused by the predominance of Indo-European languages in Europe? If so, then the non-Indo-European languages spoken in Europe should not show the predominance of *BLUE* observed in the Indo-European languages.

Figure 3, panels a, b, shows two physical geography characteristics of the individual cultures from Fig. 2, latitude and the annual dose of UVB. If the physiological hypothesis is correct, both of these graphs should correlate (with positive slope on the graph) with the use of *BLUE* (*BLACK* vs. *GRUE* vs. *BLUE*). Only latitude correlates with the use of *BLUE* in both the Old World and the New World. The idea that latitude has its effect through its effect on the annual dosage of UVB from sunlight has the difficulty that UVB dosage is correlated with *BLUE* in the Old World, but not the New World. The exposure of an individual person to UVB will be modulated by the amount of time he/she spends outdoors.

Three societal characteristics are shown in Fig. 3, panels c, d. These are Marsh's "Index of Societal Differentiation," which is a measure of the societal development of an individual culture [19]; life expectancy, which is a measure of the human development of nations; and Berry's "Technological Scale" of the economic development of nations [22]. Marsh's Index and Berry's Scale correlate with *BLUE* in the Old World but not the New World, whereas life expectancy was correlated with *BLUE* in the New World but not the Old World. These three societal effects are imperfect indicators of development. Marsh's Index is only available for the individual cultures where 166 of the languages in Fig. 2 are spoken. It is based on the per capita annual energy consumption and the fraction of males engaged in agriculture. Therefore, it will be correlated with latitude (it takes more energy to keep warm in Alaska than in Cameroon, and the short growing season makes agriculture in Siberia an unprofitable occupation). Life expectancy and Berry's Scale are available only for the nations within which the cultures are embedded. Life expectancy may show a ceiling effect in the Old World. Berry's Scale was the first principal component of an overall assessment of the economic advancement of nations, with contributions from transportation and trade, energy production and consumption, national product, communications, and urbanization. All of these societal characteristic correlates have the difficulty that none of them correlate with *BLUE* in both the Old World and the New World.

Languages that include *BLUE* greatly predominate Europe, the Mediterranean, and the Near East (Fig. 2, top panel). However, this is not entirely due to the predominance of Indo-European languages in that area. The data sets in Fig. 2 include 46 Old World languages that are spoken north of the Tropic of Cancer and west of the Ural Mountains. Of the 28 Indo-European languages and 18 non-Indo-European languages in this group, all but two use *BLUE*; one Indo-European language (Gaelic) uses *GRUE*, and one non-Indo-European language (Nenets) uses *BLACK*. Whatever is responsible for the predominance of *BLUE* in this geographical region, it is not entirely a question of linguistic heritage.

Color Dictionaries and Corpora, Fig. 3 Characteristics of the cultures or nations where the languages from Fig. 2 are spoken. Each bar indicates the value of the characteristic, averaged (± 1 s.e.m.) across cultures or nations having *BLACK*, *GRUE*, or *BLUE* as the word for blue in their languages' color lexicons. (a, b) Geographical characteristics of the localities where the 384 languages are spoken. Dark bars, absolute value of latitude, in degrees from the

equator; light gray bars, annual dose of UVB. (c, d) Societal characteristics. Dark bars, Marsh's "Index of Societal Differentiation," for 166 of the cultures shown in Fig. 2 [17, 19]. White bars, life expectancy; light gray bars, Berry's "Technological Scale" of economic development [22]. Life expectancy and Barry's Scale are shown for the nations where the languages are spoken

In spite of over 150 years of research, involving empirical corpora of color-naming data, scholarly data sets of color lexicons, and philological analyses of ancient texts, it is not well understood

why there is such great worldwide variation in the terms in the color lexicons of world languages. This topic continues to be the subject of much contemporary research.

Definition

Color Field painting is an art movement that emerged in the mid twentieth century. Artists whose works can be categorised as Color Field chose to focus predominantly on the use of color in their works almost to the exclusion of other visual elements. Color Field paintings of the twentieth century are mostly works on canvas and some artists applied color in a formal, hard-edge manner while others chose to apply color in a more organic, freeform manner. The focus on color as demonstrated by the Color Field artists continues to influence contemporary artists; however, contemporary artists often explore color across a wider variety of media.

Overview

Of the three main currents in art that emerged in the twentieth century: Expressionism, Abstraction and Fantasy, Color Field painters were inspired by

the developments in Expressionism and Abstraction [1]. The focus of Expressionism was the artist's feelings and emotional responses via their conceptual content, subject matter and painterly technique; and the focus of Abstraction was a more conceptual approach to the partial or complete non-representational depiction of subject matter depicted with more formally structured painterly techniques.

Color Field painting emerged in the 1940s and painters such as Mark Rothko (1902–1970), Helen Frankenthaler (1928–2011) and Morris Louis (1912–1962) focused on expressing emotion through painting; while Clyfford Still (1904–1980), Barnett Newman (1905–1970) and Ellsworth Kelly (born 1923) applied a more formal, structured approach to their conceptual content and composition. The predominant focus that all Color Field painters shared was the use of color as the key conduit for conveying emotional or conceptual content.

Art critic Harold Rosenberg suggested that Abstract painting represented a new function whereby the canvas became an “arena in which to act. . . What was to go on the canvas was not a picture but an event” [2, p. 22]. From Rosenberg's perspective, “a painting is inseparable from the biography of the artist” [2, p. 23]. These views were countered at the time by art critic Clement Greenberg who preferred to focus on the formal qualities such as shape, color and line rather than the act of painting. Greenberg applauded the works of Still, Newman and Rothko with their primary focus on color and Greenberg marvelled that their paintings “exhale color with an enveloping effect that is enhanced by size” [3, p. 226].

The approach of the Color Field painters reflected the nineteenth century Impressionist painter's tradition of using ‘patches’ of color to capture a scene's ambience, convey a sense of movement plus capture a fleeting moment in time. This approach came about when *Baudelaire suggested* that painters should “evoke reality, not by detailing its forms, but by using a line or patch of tone to stimulate the spectator to recreate reality through the act of imagination” (Baudelaire, 1863, cited in [4, p. 9]).

Color Field painters translated the Impressionists small-scale color ‘patches’ to much larger fields of color, encouraging their viewers to engage with their paintings on a more intimate but still static basis. Color was used to convey ambience as well as universal emotions such as *joie de vivre*, tension, tragedy and tranquillity. Rothko suggested that painting represented a “portal . . . into the vast recesses of the human psyche” and the role of color was to generate an emotional response: “I’m interested in eliciting basic human emotions – tragedy, ecstasy, doom and so on” (Rothko, cited in [5, p. 6]).

Using color as a form of communication or code, Color Field painters followed a long tradition. Vincent van Gogh (1853–1890) believed that color had the capacity to connect with the human condition: “I have tried to express the terrible passions of the human heart. . .” (Van Gogh cited in [6, p. 72]). In letters to his brother Theo, Van Gogh indicated that he attached emotional meanings to various hues and he clearly preferred strong, saturated color [7]. Similarly, Paul Gauguin (1848–1903) and the Symbolists believed that color could “act like words; that it [color] held an exact counterpart for every sensation, every nuance of feeling” [8, p. 129]. Likewise, Edvard Munch (1863–1944) used color and darker tones to help convey universal emotions such as anxiety, fear or sorrow in paintings like *The Dance of Life* (1899) and *Death in the Sick-room* (1895). Wassily Kandinsky (1866–1944) also believed that color as well as form had the capacity to communicate and he assigned certain connotations to specific colors; yellow for example represented warmth [9].

The conceptual and compositional approach of Suprematism and Russian Constructivism also had some influence on Color Field painting as evidenced by the patterns of similarity in the works of Kasimir Malevich (1879–1935) and El Lissitzky (1890–1941), and those of Rothko, Kelly and Newman. While there may be some conceptual or philosophic differences between the movements, there are strong similarities in the use of simplified geometric form as per Malevich’s *Black Square* (1915) and *Black Circle* (1915) and Kelly’s *Circle Form* (1961) and *White Curve* (1976) – see Fig. 1.

Mark Rothko (1903–1970) aimed to engage the viewer on a deeper, more personal level and “relied on large fields of color to produce solemn and elevated works” that had the power to convey something about the human condition [8, p. 314]. Eschewing other visual elements, Rothko suggested: “We may start with color”, which became the primary focus of his works (Rothko cited in [10, p. 65]).

Rothko said: “I’m interested only in expressing basic human emotions: tragedy, ecstasy, doom, and so on” [11]. The size of Rothko’s canvases, which often feature blocks of saturated color horizontally stacked, reveal his desire to create an intense experience for the viewer and he suggested that the ideal viewing distance for his works was a close arms-length distance from the canvas [5]. Rothko noted, “. . . I want to be very intimate and human. To paint a small picture is to paint yourself outside your experience, to look upon an experience as a stereopticon view or with a reducing glass. . . However, to paint the larger picture, you are in it. It isn’t something

Color Field Painting, Fig. 1 Patterns of similarity: Suprematism and Color Field painting

you command. . .” [8, p. 320]. Rothko’s paintings are a presence in themselves; so large and intensely colored that one is expected to feel their ‘Spiritual vibration’ [6, p. 72].

For Rothko, “A painting is not about experience. It *is* an experience”; an experience that transcends time and space conveying universal primal emotional experiences irrespective of gender, age and cultural experience (Rothko cited in [12, p. 57]). Rothko noted “My art is not abstract, it lives and breathes” (Rothko cited in [12, p. 50]). Key works by Rothko include *Untitled [Blue, Green, and Brown]* (1952); *Ochre and Red on Red* (1957); *Light Red Over Black* (1957); *Untitled* (1968); *Black Form No. 8* (1964), as per Fig. 2.

Barnett Newman (1905–1970) used the color palette of the De Stijl movement and the Bauhaus in a completely different way: “Why give in to these purists and formalists who have put a mortgage on red, yellow and blue, transforming these colors into an idea that destroys them as colors?” (Newman cited in [10, p. 27]).

Newman commented that “The central issue of painting is the subject matter. . .my subject is anti-anecdotal” whereby a painting is more self-sufficient and independent with color and shape standing alone and prominent without reference to anything else [13].

Newman’s paintings often feature vertical lines that serve as “an act of division and creation” [between one color plane or reality and another]. . .the “zip” has become the single most dramatic event in the composition” [14, p. 77]. Key paintings by Newman include *Dionysius* (1949); *Voice of Fire* (1967); *Who’s Afraid of Red, Yellow and Blue?* (1966) and *Midnight Blue* (1970), as per Fig. 3.

Helen Frankenthaler’s (1928–2011) work became synonymous with a freer, more sensuous approach to Color Field painting [15]. Frankenthaler’s works are large and she applied color in a technique known as ‘soak stain’, wherein oil painted was diluted with turpentine so that the color soaked into the canvas creating halos of color.

Color Field Painting, Fig. 2 Color Field paintings, Mark Rothko

Color Field Painting, Fig. 3 Color Field paintings, Barnett Newman

Color Field Painting,

Fig. 4 Color Field paintings, Helen Frankenthaler

The free-form and more sensuous nature of her paintings, prompted Hughes to suggest that “Landscape, imagined as Arcadia, remained the governing image in Frankenthaler’s work, and her titles often invoked the idea of Paradise or Eden [8, p. 154]. Key works by Frankenthaler include *Mountains and Sea* (1952); *Yellow Span* (1968) and *Nature Abhors a Vacuum* (1973), illustrated in Fig. 4.

The use of color by the New York-based Color Field painters influenced the West Coast painters as well as artists further afield, some of whom used new materials and techniques.

Karl Benjamin (1925–2012), whose work featured in the exhibition ‘Four Abstract Classicists’ (1959–1960), contributed to the US West Coast response to New York Abstract Expressionists. Benjamin’s work shared similarities with the Color Field painters and his works feature a sense of movement and vibrant optimism characteristic of the ‘California Cool’ aesthetic of California during the 1950s and early 1960s.

The use of color in Benjamin’s work in conjunction with the repetition of shape and line

creates works that are “fixed and stable” but in a state of “continuous flux” and convey a strong sense of movement and vitality [16]. Key works include *Black Pillars* (1957), #38 (1960), #7 (1966) and #7 (1986) illustrated in Fig. 5.

Lorser Feitelson (1898–1978), whose works also featured in the exhibition ‘Four Abstract Classicists’ (1959–1960), painted planes of color interspersed with a fluid use of line that imbued his layered abstract works with a strong sense of graceful movement, vitality and dynamism. Key works by Feitelson include *Hardedge Line Painting* (1963); *Untitled* (1965) and *Untitled* (1967) and *Coral and Blue Abstract* (1967), illustrated in Fig. 6.

Richard Paul Lohse (1902–1988) created color investigations that “deploy the full range of spectral colors in endlessly inventive series” [10, p. 43]. Lohse painted individual colors in large grid formations to illustrate the notion that “the crowd contains the possibility of the individual” and also to highlight that color juxtaposition had the capacity to annul the “sovereignty of the [individual] color square” (Lohse cited in [10, p. 45]). Lohse’s works vary in scale from relatively small

to very large, to enable an in-depth investigation of color and color juxtaposition [17]. Key works include *Progressive Reduction* (1942–1943); *Thirty vertical systematic color series in a yellow rhombic form* (1943, 1970) and *Thematic series in 18 colors* (1982) – see Fig. 7.

In the twenty-first century, artists have translated the idea of ‘patches’ of color and the approach taken by Color Field painters into a variety of new and different formats and mediums, often incorporating light, automated movement as well as the mechanics of human perception.

Gerhard Richter (born 1932) adopted the grid format of the early Modernists and imbued this with an abundance of color that could be grouped at random, as per the series of large-format paintings: *256 Colors* and *4900 colors* [10]. Richter’s random grouping of color mimics the complexity of color in nature and he painted several versions of *256 Colors* (1974) plus re-colored them in the 1980s. The work *4900 Colors* (2007) comprises 196 equal-size panels each containing 25 squares of color, as depicted in Fig. 8.

Australian Robert Owen (born 1937) also prefers depicting color via a grid format as it is “capable of providing infinite variations” and suggests that his paintings are “about levels of feelings, orders of sensation, shifting sequences of,

time and rhythm” [18, p. 9]. In *Cadence* (2003), Owen has depicted the range of his emotions measured using color tabulation. Responding to a competition for a public work by the Bureau of Meteorology, Owen said: “I thought, if they can measure atmosphere, I must be able to measure emotions. So, using a color tabulation, I intuitively picked how I felt every half hour during the day” [19]. The juxtaposition of color and constant variation triggers a strong sense of movement across the work. *Sunrise #3* (2005), painted in-situ in the Museum of Contemporary Art, Sydney, explores the impact of color by taking the Impressionists notion of ‘patches’ of color and translating this into a much larger work (Fig. 9).

Los Angeles-based Dion Johnson (born 1975), whose works are reminiscent of the works of Benjamin and Feitelson, focuses on the interplay of color (*Gliger*, 2011). Colors converge and side-swipe each other, setting off color juxtapositions that add a sense of dynamism and vitality to Los Angeles-based Johnson’s large-scale canvases. Works such as *Velocity* (2012) and *Wild* (2012) feature hard-edge yet malleable color, as depicted in Fig. 10.

Rebecca Baumann (born 1983) has adopted the Color Field painters approach to color but added

Robert Owen

mechanised movement. In *Automated Color Field* (2011), the automated movement brings ever-changing random juxtaposition to Baumann ‘patches’ of color. Baumann is interested in the

way ‘color is both universal and subjective’ with the capacity to ‘move people beyond cognitive and conscious thought’ (Baumann cited in [20]). Baumann acknowledges the changeable nature of

 Brendan Van Hek (right)

human response and her artworks feature “apparently random change(s) across the field, suggesting the flux in both our inner emotions

and the outside world” (Baumann cited in [21]), see Fig. 11 (left).

Brendan Van Hek (born 1968) uses found neon such as remnants of advertising signs and symbols

to create works like *Color Composition #3* (2013). In doing so, Van Hek subverts the original neon messages to create works that reflect the visual landscape and clutter of the twenty-first century: “*Color Composition # 3* started as an idea about landscape – a horizon line and the movement of forms along, below and above it (Fig. 11, right). What the work has developed into is one that describes a landscape of noises, activity, words, streaking taillights, constant action and movement – the city” (Van Hek cited in [22]).

Color Field Painting: The Influence on Design

The unique approach to color by the Color Field painters influenced art and applied design from the mid twentieth century through to contemporary practice. Before the advent of digital design, many designers were trained in colour mixing and application techniques influenced by the Bauhaus color curriculum and especially techniques devised by Josef Albers, Johannes Itten and

Color Field Painting,
Fig. 12 Film posters
designed by Saul Bass

Color Field Painting, Fig. 13 Poster and CD cover design inspired by Color Field painting

other former teachers and students of the Bauhaus. As a result, across all areas of applied design including graphic design, textile and fashion design, practitioners often used gouache paint to create designs, mixing colors as per the RYB color model.

Film posters designed by Saul Bass feature a hard edge, Color Field painting aesthetic: *The Man with the Golden Arm* (1955); *Anatomy of a Murder* by Saul Bass, (1959); *The Cardinal* (1963) and *The Human Factor* (1979), illustrated in Fig. 12.

Similarly, posters for *Before Sunrise* (1995), *The End of Summer* (2013) and *Rush* (2013) as well as recent ECM CD covers including Keith Jarrett's *Back Hand* (1974) and *Rio* (2011) are reminiscent of the Color Field paintings of Barnett

Newman and Ellsworth Kelly as well as Mark Rothko, as illustrated in Fig. 13.

Color Field painting also influenced textile and fashion design. The impact of this art movement continues with the fashion trend for color blocking that emerged in 2010 as well as the textile designs of Satu Maaranen (2011); Marimekko Sabluuna dress, Spring 2013 and the Gucci Sprint/Summer 2013 collection, illustrated in Fig. 14.

Color Field Painting: The Impact on Immersive Color Installations

Color Field painters influenced many subsequent artists, who create works that focus on color with

Color Field Painting, Fig. 14 Textile designs (Z. O'Connor) and fashion designs inspired by Color Field painting

the aim of connecting with the viewer and encouraging a deeper level of engagement often on a more intimate, immersive basis as per the works of Verner Panton, Peter Jones, Olafur Eliasson, Gabriel Dawe, Matthew Johnson and James Turrell. A common theme of these artists is exploration of the interface between color and human response in ways that leave the viewer enriched with a greater understanding about color.

Immersive works and projections are not viewed at arm's distance but often envelope the viewer, and elicit not only emotional response but trigger perceptual responses that form part of the work as a whole. While some of these works remain static, some works, such as those of Olafur Eliasson, involve a degree of 'radical subjectivity' on the part of the viewer, thereby making their perceptive subjectivity a component of the work [23].

Definition

A sense of accord and balance among colors in a visual composition or design, resulting in a positive affective response and/or cognitive judgment about color combination.

Color Harmony Theories

Many theories about color harmony have evolved since antiquity across different fields including art, design, psychology, and physics. Each of these has a different focus, and hence there is little consensus in terms of defining and describing the construct “color harmony.” Most theories about color harmony are highly prescriptive, and this is their weakness – they assume that responses to color are deterministic, uniform, universal, and fixed irrespective of context rather than idiosyncratic, less deterministic, and open to the influence of factors relating to culture and context.

The problem of color harmony has long been regarded as an esoteric matter for the artist. But since the advent of interdisciplinary research on colors, color harmony has become an object of scientific research giving rise to several theories. These theories emphasize different relations between the role of color harmony in environment and man, his culture, and his message and consider these as the exclusive laws of harmony. The scientifically established theories deal almost exclusively with the first level of the content of the concept of color harmony. They research the connections, which are mostly the same for all people. These relations express interactions between color perceptions, which can be described, in sum, in terms of relations between color perception parameters: hue, saturation, and lightness of harmonizing colors. These relations lend names to the harmony types such as complementary harmony, triadic harmony, scale of equal saturations, and others.

Color Harmony: A Twenty-First-Century Approach

Color harmony is a complex notion because human responses to color are both affective and cognitive, involving emotional response and judgment. Hence, our responses to color and the notion of color harmony are open to the influence of a range of different factors. These factors include individual differences (such as age, gender, personal preference, affective state, etc.) as well as cultural, subcultural, and socially based differences which give rise to conditioning and learned responses about color. In addition, context always has an influence on responses about color and notion of color harmony, and this concept is also influenced by temporal factors (such as changing trends) and perceptual factors (such as simultaneous contrast) which may impinge on human response to color. The following conceptual model illustrates this twenty-first-century approach to color harmony:

$$\text{Color harmony} = f(\text{color } 1, 2, 3 + n) * (ID + CE + CX + P + T)$$

wherein color harmony is a function (f) of the interaction between the color/s (col 1, 2, 3 + n) and the factors that influence positive aesthetic response to color which include the following: individual differences (ID) such as age, gender, personality, and affective state, cultural experiences (CE) and the influence of cultural and social conditioning, influence of the prevailing context (CX) of color(s) which may include setting and ambient lighting, intervening perceptual effects (P) such as simultaneous contrast, and, finally, the effects of time (T) in terms of prevailing social trends [1].

Harmony as a Balance Between Psychophysical Forces

According to the first theory on color harmony, the rules for producing color harmony experiences are determined by the mechanics of color vision. The trigger of the theory has been the phenomenon of successive contrast: longer

observation of green results in a red afterimage. Investigating this phenomenon, Rumford [2] has established that colors of successive color contrast mixed in an “appropriate proportion” in the Maxwell disk are resulting in a medium gray color. Goethe has built his theory of color harmony based on this observation. He thought the colors of successive contrast and simultaneous contrast are identical [3]. Therefore he stated that the “appropriate proportion” established by Rumford expresses the magnitude of color surfaces creating harmony experiences.

Chevreul, the French chemist, arrived at similar conclusions, stressing the role of complementarity in creating harmony, supporting his theory by successive contrast phenomena [4]. His message transmitted by Delacroix was translated by Seurat and Signac into the practice of painting [5–7]. Seurat himself experimented with harmonies, recapitulating his results by stating that harmony is a unity of opposites and similarities, a principle serving as the theoretical basis of pointillism.

Goethe’s theory has appeared with the mediation of Hölzel [8] in the works on the theory of art written by Kandinsky, Klee, Itten, Albers, and Moholy-Nagy [9–13]. Itten, in his book written for the students of the Bauhaus school, has fixed this proportion in relation to main colors [14]. He established that the appropriate mutual proportion of the colors yellow, orange, red, violet, blue, and green is as follows: 9:8:6:4:6.

Krawkow has demonstrated by experiments that the colors of successive contrast are not identical to the colors of simultaneous contrast [15]. This experimental result has refuted the conclusions of harmony theories originated from Rumford. Successive contrast is a physiological phenomenon, while the simultaneous color contrast is an aesthetic influence.

Harmony as Arrangement of Colors in Scales

It was observed by textile dyers and printers that mixing a color with white, gray, or black in different proportions led to very attractive, harmonic color complexes. It was one of the secrets of the

trade of painters to make each of their colors dull by admixing a color in different proportions, helping colors in the picture to form harmonic complexes. Both approaches arose from the recognition that colors with uniformly varying saturation or lightness, i.e., those forming a scale, appeared harmonic. This observation was the starting point of the second generation of theories on harmony.

The first scale of color harmony was constructed by Newton and published in his *Optics* in 1704 [16]. Dividing the spectrum into seven colors, he paralleled it to the musical scale. His idea was further developed by Hoffmann in his book published in 1786 [17], explaining color harmonies with the aid of acoustic analogies [18]. In 1810, the painter Runge suggested and attempted to develop a unified system of musical and color harmonies. These ideas misdirected the research on color harmonies for a long time since even their followers were concerned only with hue scales.

Ostwald [19] and Plochère [20] were the first to define the arrangement in scales by writing relationships between saturation and lightness. Scale members were described by Ostwald as additive color mixing and by Plochère as subtractive color mixing components. In his theory of harmonies, Ostwald pointed out that in order to find every possible harmony, possible orders in the color solid have to be found [21]. The simpler this order, the clearer and self-evident is the harmony. There are essentially two of these orders: those in the equivalent color circle and in the isochrome triangle. This latter statement expresses the dependence of harmony on the uniform variation of saturation and lightness. Ostwald's theory was progressive in that it connected the laws of color harmony with the relations between exactly measurable components. For the achromatic scale, the laws of harmony are coincident with experience. In other respects, however, experience fails to support his findings. The essential deficiency of his laws of harmony resides in his color system. Color points of his color system represent color perceptions related only by mathematically

definable quantitative variations of color mixing components. The interrelation between them comprises no perceptually equal or uniformly varying intervals.

Henri Pfeiffer, a painter starting from the Bauhaus school, later a graduate from the University of Cologne who became professor at the École d'Architecture in Paris, considered the creation of a color harmony system as his chef d'oeuvre. He started from the acoustic meaning of "harmony" – namely, that the three main tones *do* (*C*), *mi* (*E*), and *sol* (*G*) of a vibrating chord are proportional in a way that the chord length for *mi* (*E*) is the harmonic mean between the chord lengths for *do* (*C*) and *sol* (*G*). The algebraic generalization of this rule was applied for determining color harmonies. Referring to tests by Rosenstiehl [22] and Fechner [23], Pfeiffer established that lightness intervals of the logarithmic scale are in a harmonic relation and called this scale a harmonic scale. Then he deduced correlations between the logarithmic scale and the scale obtained by the golden section. In his book he described in detail his tests using Plateau and Maxwell disks to create harmonic scales. He classified his scales into two groups: isochromic or equal hue scales and isophanic or equal lightness scales. First he defined each kind of harmony and then presented its mode of construction by means of a revolving disk, followed by the analysis of the psychic character of harmony. Characteristic of his work are his chromatologic tables, with the aid of which he defined harmonizing color groups.

Harmonic scales can be developed not only according to laws of additive or subtractive color mixing but also by taking perceptually uniform intervals between colors. Colors of the Munsell color system constitute such perceptually uniform hue, saturation, and lightness scales [24, 25]. In his book, Munsell writes that a color scheme along a "path" is always harmonious.

Color Harmony as an Aesthetic Experience

According to the most recent theories of color harmony, the principles related to the establishment of color harmony experience could be

recognized only by statistical surveys based on a multitude of experiences. Their experiments are related to determined population each time. Ultimately they intended to create a system which may predict whether a given color composition will be judged by the members of a defined population as harmonic or not.

Moon and Spencer developed a model to quantify color harmony by statistical methods based on surveys [26, 27]. The main elements of Moon and Spencer's color harmony model are color intervals, area ratio, and aesthetic measurement. The aesthetical measure developed by Moon and Spencer, despite of its controversial results, provides a basic quantitative approximation of the problem in a field possessing so far only qualitative contemplations lacking verification. According to Moon and Spencer, the colors can be harmonious if the color difference is determined between the individual components. The definite color difference is defined as an interval. The magnitude of intervals defined by Moon and Spencer differs by hues. According to Moon and Spencer, a harmonic balance between color samples can be only reached if the scalar momentums related to an adaptation point in a linear space are equal to or are products of each other. The adaptation point is a point of the linear color space which corresponds to the adaptation state of the eye, normally it is medium gray.

More people have dealt with the definition of the magnitude of those intervals between members of a scale being judged as harmonic one. Dimmick [28] and Boring [29] determined the smallest of such intervals. They found that for an interval less than a certain value no harmony can any longer develop. Moon and Spencer found that these intervals were different for different hues. To examine and confirm this observation, Mori et al. [30] made experiments, and their findings agreed with those of earlier tests on lightness intervals by Katz, Gelb, and Granit [31–33].

In fine arts, intervals between colors in a picture have always been important and

characteristic of a given painter. Matisse [34] has always striven for uniform intervals in his color compositions. As Mondrian [35] wrote it in 1945, "For millennia, painting expressed proportionality in terms of color relations and form relations, achieving but recently the finding of proportionality itself."

The results of a line of experiments registering the judgments of more than 50,000 observers have been used by Nemcsics [36, 37] to create the color harmony index number system. The system denotes every existing couple of colors with a number between 0 and 100. This number expresses the magnitude of harmony of a color couple felt by different groups of people, i.e., how much is the harmony content of the color couple. The conclusions of the color harmony theory of Nemcsics are the following:

1. Between the Coloroid saturation and luminance values of color compositions felt harmonic, there is an identical number or logarithmically changing number of harmony intervals.
2. The members of compositions consisting of identical hues felt harmonic are located on straight lines of the actual axis section of the Coloroid color space [38].
3. The magnitude of harmony content of color compositions located on straight lines of the Coloroid color planes spaced at identical harmony intervals is felt different depending on the angle in relation to a straight line chosen as starting line being perpendicular to the gray axis.
4. The harmony content of hue pairs is higher than that of the others if they decline from each other in the Coloroid color space less than 10° , or decline between 30 and 40° , or decline between 130 and 140° , or their declination is near to 180° .
5. Both for men and women, it is valid that the intensity of the harmony experience of a composition is in synchronism with the preference of the colors in the composition bearing harmony.

Philosophical and Historical Overview

A great deal has been written about color harmony, from Chevreul [4], who was convinced that many different color hues and their harmony could be defined by means of the relationship between numbers and his color system as an instrument to find “harmony of analogy” and “harmony of contrasts” or from the numeric naming system of Munsell (1905) [24, 25], based on the criterion of perceptual uniformity and balance, passing through Bauhaus theories (1919–1933), until sophisticated contemporary three-dimensional color softwares.

However, in philosophical terms color harmony is a highly variable concept that is open to the influence of different including individual differences (such as age, gender, personality, affective state, and so on), cultural and subcultural differences, as well as contextual, perceptual, and temporal factors. In addition, from an ontological perspective, many early theorists championed an understanding of color harmony that was universal in nature and strictly deterministic, that is, color harmony was an effect that occurred for all people on a highly predictable basis irrespective of the context or situation. In the twenty-first century, theorists tend to take a more idiographic, stochastic view about color harmony. That is, the highly subjective nature of responses to color is acknowledged, and responses about color harmony are understood to occur on a more individual and less universal basis and are more likely to be probabilistic rather than deterministic and predictable [1, 39].

The art historian and theoretician Brandi (1906–1988) [40] writes that “the significance of words is not things, but the pre-conceptual scheme of things . . . , in other words, a summary of knowledge of things according to a given society”; the same is for the taste of color, connected with the geographical, historical, and social environment. This notion, which dates back to the ancient Greek philosophers, was also expressed by Hume (1711–1776): “Beauty in things exists

merely in the mind which contemplates them” [41].

Color Harmony as Historical Model

Since all that relates to matters of taste and aesthetic pleasure belongs to the cultural sphere – and is therefore conditioned by, associated with, and subject to myriad factors – the definition of chromatic harmony periodically renews its model, creating new codes for new contents.

In olden times man sought perfection of his surrounds built on symmetry, as in the numeric unit of measurement of Greek temples, whose aesthetic quality comes about through internal, independent ordering of the whole. During the Renaissance, the architect Alberti (1404–1472) [42] defined beauty as “a harmony of all the parts . . . fitted together with such proportion and connection, that nothing could be added, diminished or altered, but for the worse”.

The different societies of the world have given rise to its own chromatic spectra, applying different criteria of harmony to the juxtaposition of colors, in a dynamic scheme, related to two essential properties: mimesis and ostentation.

Color Harmony as Mimesis

As in linguistics, there is onomatopoeic harmony, consisting in imitation of natural sounds by means of a phonic impression of the linguistic form, and in the animal kingdom, some creatures take on the chromatic features of the surrounding environment in order to camouflage themselves, so too in certain cultures, manufactured articles are modeled on the colors of the materials of the place in which they are introduced, thereby creating imitative harmony. Uniformity and similarity refer to something preexisting and therefore evoke aesthetic pleasure by reason of the fact that they are pleasing and reassuring.

Color Harmony as Ostentation

And yet, on the other hand, chromatic pleasantness is sought by enriching places with missing colors, so that full-bodied, vibrant, and rich colors stand out against the uniform backgrounds of

landscapes, acting, contrary to imitation, through differentiation. In both aesthetic models, mimesis and differentiation, there is harmony when there is unity in multiplicity, ordering the various parts into a coherent whole, when colors in a multi-chromatic background establish a dynamic and balanced relationship among dimension, distribution, saturation, whiteness, and blackness.

Color Harmony in the Society of Permanent Colors

Now that chemical colors deriving from processing petrochemical synthesis can be reproduced limitlessly, there has been a revolution in perception, which initially struck the eye of the viewer but which later accustomed the viewer's eyes and mind to their fixity and unchanging nature. The environment has again taken on stable yet inert colors.

The invention of the tin tube replacing an animal's bladder, together with chemical colors, has revolutionized painting, making it more convenient *plain air* (outdoors) and allowing the experimentation of the *pointillists*, in the same way as industrial enamel paints have made possible the *dripping style* painting of Pollock (1912–1956) [43], while quick-drying acrylic colors have given rise to a certain taste for Warhol's (1928–1987) [44] and pop art's wide-ranging, flat, uniform painting style.

It can be claimed that “abstract art was born with synthetic color, which became the most important and absolute principle of abstraction” [45].

While Max Bill (1908–1984) [46] sought chromatic harmony in laws of spatial values and in laws of color movement, distributed on the basis of proportions, Hartung (1904–1989) [47] was inspired by him in his appreciation of the energy of vinyl colors, which were scratched with different instruments and sprayed with compressors.

Later, after the invention of pearlescent and iridescent paints containing flakes of mica coated in titanium oxides, American minimalist painters covered surfaces with new changeable metallic

colors, freed from fixatives. Today, *acrylic* resin and silicone made possible the work of Pesce (1939) [48], where the colors blend in three dimensions.

In this concept of harmony, colors are being considered all the more beautiful when they are able to create a perceptive illusion and hide the nature of the material under a uniform permanent patina.

Color Harmony in the Society of Permutable Colors

Nowadays, digital screens are shifting vision from substance to light, prompting an adjustment toward a chromatic panorama characterized by intangibility and exchangeability.

In art, colored lights alter the perception of the physical place and introduce another space-time dimension. While Flavin (1933–1996) [49] was among the first to compose environmental works using fluorescent neon tubes, in which floors, walls, and ceilings seemed canceled by the colored light, embracing viewers in a suspended dimensions, nowadays digital media makes limitless experimentation possible. Viola (1951) [50], a veritable maestro, treats his works with a chromatic pattern making them similar to a painting, with a soft painting-like light running through them, a light that immerses the viewer in an emotional, sensorial experience taking place in an intermediate, part-natural and part-artificial space, which is both real and unreal. Toderi (1963) [51], an up-and-coming Italian video artist, transforms her urban film shooting into luminous stellar spaces, linking heaven and earth in a pulsating flow.

Color harmony nowadays is becoming dematerialized, exchanging artificial light which cancels materials, space, and time.

Conclusion

Giulio Carlo Argan wrote that “recognizing beauty is an act of justice and a sentimental act, meaning an act which confers value” [52].

In this way, as all that relates to matter of taste and aesthetic pleasure belongs to the cultural sphere – and is therefore conditioned by, associated with, and subject to myriad factors – so also the definition of chromatic harmony is related to culturally accepted notions of taste and beauty. Given the changeable nature of notions such as beauty, taste, and aesthetic pleasure, any models to predict such are open to periodic renewal, creating new models or codes for new contexts.

Definition

An aspect of hospital buildings in promoting the sense of well-being and comfort for all users besides the excellence of medical care

Introduction

Both the clinical and nonclinical areas of hospitals are created to promote the recovery process of patients by enhancing a sense of well-being for all users. The ambience of physical environments in hospitals – such as the entrance, reception areas, waiting areas, corridors, consulting rooms, and wards – can be attractive and provide visual stimulation. Creating ambience in such physical environments involves careful consideration of surface materials and paints, furniture, decoration, natural light, and artificial lighting. These diverse elements share an inseparable quality: color. Color affects user perception of the surroundings, thereby reducing general levels of stress especially by encouraging positive distraction and social support [1] as well as promoting confidence and safety. It serves in spatial orientation as a powerful tool used in coding, navigation, and

wayfinding [2]. Color also affects patients' recovery rates by improving the quality of experiences of patients, staff, and visitors [3]. Color design can be utilized for the benefit of patients, staff, and visitors in locations mutually occupied by persons of all ages who also have varying levels of health and mobility [2, 4].

Role of Color Application in Hospitals

An appropriate application of color can succeed in establishing a friendly, welcoming atmosphere comfortable for all [2]. Although hospital design necessarily should incorporate ease of access and inclusion of all kinds of persons, special attention needs to be paid to elderly as well as visually impaired persons, for whom ensuring optimal color application in their environment is crucial. Color applications are mainly important for the elderly and visually impaired people as such persons require clearer cues and need more time to comprehend visual information. Such users may also be less confident about occupying those environments [2, 5]. For both the elderly and the visually impaired, colors and textures of walls and floors are of the utmost importance in their navigation within the hospital environment without stress and enabling that they can develop a mental map for orientation in their surroundings [2]. Color contrast also needs to be provided in order to prevent accidents and establish spatial clues for wayfinding. Some of the colors, especially blue and green, become difficult to discriminate since human eye lens transmittance decreases with increased age [6]. Thus, color applications in hospitals should be carefully done for better color discrimination. For elderly and visually impaired people, color combinations with yellows, oranges, and reds can be used to improve visual performances.

Likewise, just as the elderly and visually impaired, children need to be able to understand their surroundings both intuitively and cognitively. Young children make associations with color more than forms. As Dalke et al. [2] indicated, children are less conscious about form but they can easily grasp colorful objects. This means that designing

environments with appropriate colors is especially important in children's hospitals. Such an environment should not only be interesting to children, but also created at their scale since children often experience fear and boredom in hospitals. Colorful and interesting playground areas can be positively distracting and serve to reduce negative emotions and lower stress levels.

Color can be used practically and functionally in accommodations and for wayfinding for patients and visitors, serving to make such spaces and orientation even more interesting. It is often difficult to navigate in such an unfamiliar environment. This difficulty can cause stress. As already mentioned earlier, color can be applied in signage, making wayfinding and mental mapping easier (Fig. 1). Especially, both the visitors and patients who enter the hospital may be understandably upset and preoccupied because of the urgency of their situation, and therefore, special attention needs to be given to establishing clear accessibility, signage, and other clues for orientation [2]. As well, generally, a hospital is complex, which makes wayfinding difficult [4]. Color coding can be employed to institute navigation routes, spatial hierarchies, and differentiation among facilities, a tool which enhances visual perception, visual attention, cognitive mapping, and the understanding of form. According to Dalke et al.

[2, 7], in coding colors, the variety of colors should be limited to minimize wayfinding confusion. A neutral color palette can be used since it directs user attention to accent colors in signage, landmarks, and important junction spaces [8]. However, study conducted with elderly people indicated that neutral color schemes (gray and beige) decrease the attention, whereas tones of blue and red enhance their navigation performances [9].

Reception, entrance, and waiting areas are important spaces where users can accommodate themselves to the hospital environment. Reception and entrance areas are perceived first, and when distinguished as landmarks, they can immediately help users to get oriented, e.g., through the usage of a strong color behind the receptionist [2] and distinctive colors in the entrance area. However, using dark colors are not advisable since they can negatively affect perception in narrow spaces and may generate confinement sensation [6]. An optimal choice of furniture, color, and lighting in entrance and waiting areas will not only serve to reduce stress [10], but also will create a comfortable, homelike atmosphere.

Care areas should be reassuring and provide a sense of excellent medical care combined with physical and emotional comfort [10]. Sensations of relaxation, comfort, cleanliness, and hygiene are important in hospital environments. In contrast

Color in Hospitals,

Fig. 2 Summary of color applications in hospitals (figure created by the authors)

to common usage and a widespread preference for using white in the treatment of all surfaces of care areas, material and color variety can create a home-like atmosphere that promotes a sense of well-being. At the same time, using lighter colors is more necessary in narrow spaces [6]. Light colors increase sense of spaciousness which enhances well-being. As Delcampo-Carda, Torres-Barchino, and Serra-Lluch [6] highlighted, using achromatic colors on most of the surfaces can create monotony which negatively effects the recovery rates of patients and also can decrease morale of staff and visitors due to lack of stimulation and interest. Thus, colors can be used to give character to a space [6] to assist users' decision-making processes while solving a spatial problem related with wayfinding [9].

Color is an intrinsic characteristic of every material, and it is an inseparable tool in design. It literally covers and permeates all materials and its surfaces. Entailing everything from all materials, light, paint, art, and ambience, color is an essential component of the environment both aesthetically and functionally. It affects perception, emotions, and well-being. Color enhances the quality of life, i.e., variation of the hue or saturation of color has a positive influence on mood and human behavior. Color improves ambience and thereby increases the quality of experience, and it also reduces stress and creates safe

environments since color eases navigation, wayfinding, and the communication of information through color coding and the application of color in signage in public environments. Color, as one of the foremost features of hospital buildings (Fig. 2), has a role in patients' and other users' well-being and overall experiences in healthcare environments.

Definition

An aspect of school and office environments for improving visual processing, reducing stress, and enhancing task performances of all users.

Role of Color Application in Schools

Schools, where students spend most of their time, play an important role not only in their education but also in their physiological and psychological developments. Physical qualities of schools, described as the third educator, have vital effects on students' learning outcomes including place awareness [1]. With age, place awareness develops very rapidly [2, 3], as the young children are getting older, they start to obtain more information about their environments. Also, their abilities to understand and detect changes in the spaces improve too [4]. For an effective wayfinding, students should be able to relate spaces to other spaces and understand the basic layouts of space organizations, which often depend on the availability of environmental information [5]. Spatial learning begins in childhood but children need support while they are navigating themselves. One of the supports that can be provided by the physical environment is the usage of colors on surfaces, landmarks, furniture, etc. Besides its aesthetic and physical qualities, color is a powerful navigation tool.

The quality of school environment plays a significant role in students' way of learning [4, 6]. Hence, color in schools creates visual interest and it is one of the most important built environment elements in promoting navigation. Color in schools certainly improves children's wayfinding and spatial orientation abilities [7]. According to the findings of Read, children's sensory stimulation can be enhanced by using warm hues and bright accents in school environment surfaces [7]. It should be noted that color is a guiding tool, which should not dominate the environment [4]. Color can aid students' sense of security and safety since they need to know where they are in a complex building. Children's orientation and spatial cognition performances

Color in Schools and Offices, Fig. 1 Indoor landmark. Elif Helvacioğlu, 2007

can be improved by creating visual attraction points, i.e., indoor landmarks (Fig. 1) [4].

Color is not just the stationery of a surface [8]. By using color in classroom surfaces visual interest can be provided. Besides evoking visual interest, color can enhance children's cognitive performances. A study conducted by Brooker and Franklin [9] examined the effects of chromatic and achromatic colors in children's cognitive performances and found a positive impact of red in increasing their cognitive performances. Also it can be used to break monotony in classrooms where students easily get bored. Carefully applied and sparsely used colors can make classroom environments stimulating and supporting. In the classroom, side walls and the rear wall should have non-distinct colors where the front wall should benefit from a distinct color (Fig. 2). The purpose is to attract students' attention on what they have in their front and to rest their eyes when raising them up from the desk surface,

giving them a clear color contrast between the board, walls, materials, and the teacher [8].

In general, colors in a physical environment work as communication tools between people and the objects or surfaces around them [10]. It helps space recognition, encoding, and recalling while building mental maps of a physical environment. Color in schools (Fig. 3) provide optimum environments for children, which increases their visual processing, decreases stress, and improves brain development by creating challenges [11].

Role of Color Application in Offices

Colors are everyday interior architecture elements, which are inevitably affecting users. Kwallek et al. [12] highlighted their ubiquitous nature in our environments. Smith [13] discussed effects of colors on man-made environments such as interior architecture, architecture, urban design, etc., for their meanings and experiences in the context of COLPE (color, person, and environment) relationship and indicated that color, as an immanent environmental element, has an influential role. Kwallek et al. [14] underlined long hours that people spend in office spaces during their waking times, therefore their importance on users. Office spaces, in which people are spending their daytimes, have been in everyday life scene of people for many centuries. Moreover, office spaces are inherently evolving interiors depending on recent technologies and innovations that make them more ambiguous for color choices than other interiors. Contrary to other interiors, technologies and innovations can affect office spaces more directly and rapidly, since the function and duration of occupancy of technological developments are impactful in shaping the definition of office spaces. Last decade has witnessed not only massive usage of computers in office spaces but also different technologies such as mobile devices which provide more flexibility. Definition of office spaces are extended further and become part of different interior types in connection with many people starting to work from their homes or other public spaces. Fortunately, many enterprises do not miss the

Color in Schools

Color in schools creates visual interest, decreases stress, and improves brain development by creating challenges.

Carefully applied and sparsely used colors can make the classroom environments stimulating and supporting. In the classroom, side walls and the rear wall should have non-distinct colors where the front wall should have a distinct color.

Using warm hues and bright accents in school environment surfaces improves children's wayfinding and spatial orientation abilities.

Color in Schools and Offices, Fig. 3 Summary of color applications in schools. (Figure created by the authors)

opportunity and to satisfy their costumers' tendency to work out of their offices or homes, they include working/studying parts in their interiors.

Wall colors in interiors have been explored by different researchers in different contexts [15–18]. Similar to these studies, office interior colors

have been investigated by different researchers who focused on wall colors and their effects on occupants [12, 14, 19–22]. The most common and interesting feature of these studies is that they were conducted on a one-to-one scale experimental settings. The same feature was mentioned by Jalil et al. [23] that 11 of 12 studies on office/workspace, which the authors reviewed, had been conducted in one-to-one settings. These studies constructed the office environments on a one-to-one scale because it might be easier to simulate the offices' function and the activities done in those offices.

Previous studies demonstrated that colors have effects on arousal [14, 20, 21] mood [14, 24], productivity/performance [14, 20–22], appraisal [22], and satisfaction, and perceived performance [12] in office interiors. Kwallek et al. [19] showed a significant relationship between color of office interiors and number of errors during proofreading task in their study, which investigated nine different monochromatic colored offices. Their participants made more errors in office with white walls than blue one and red one separately, and light colors cause higher number of errors than darker colors in offices [19]. In addition, male participants felt more anger and depression in higher saturations whereas female participants felt more anger and depression in lower saturations [19]. Another previous study proved that environmental sensitivity and color schemes are an important determinant, which can affect mood and productivity of workers [14]. Low screeners, who cannot easily ignore irrelevant external elements in the environment, showed more dysphoria in red office than high screeners, who can eliminate irrelevant external elements [14]. White and blue-green office wall colors increase satisfaction and perceived job performance, and high and moderate screeners reported higher satisfaction and perceived performance [12]. Moderate screeners have enhanced performance than high and low screeners in blue-green office [20]. Küller et al. [21] compared three similar one-to-one scale experiments about office spaces: the first experiment investigated gray and colorful interiors, the second experiment explored red and blue interiors, and the last experiment investigated red and blue interiors for both clerical

and creative tasks. Their findings revealed that higher chromaticity increases perceived complexity and decreases perceived unity, blue interiors showed higher potency, and according to measurements, which were based on brain activities of participants during three experiments, colorful interiors are more arousing than red interiors which are more arousing than blue and gray interiors [21]. It is worth to indicate that personality (being introverted or extrovert) and nature of task (clerical tasks or creative tasks) are affected by interior colors differently and the authors proposed usage of warm colors to increase arousal. Öztürk et al. [22] proved that chroma has a significant effect on task performance and found that chromatic interiors cause more pleasant, more attractive, more satisfying, and more dynamic appraisals. Moreover, Öztürk et al. [22] stated that their findings about chroma effect on office interiors are parallel to findings of Küller et al. [21]: chroma has important effect on users' arousals in office interiors, achromatic office interiors are evaluated as more harmonious [22] and has higher unity [21], whereas chromatic ones are more dynamic [22] and complex [21]. Van der Voordt et al. [25] stated that the fundamental BOSTI study [26] revealed that low chroma colors were preferred more as office wall colors. According to Van der Voordt et al. [25] white is the most preferred color for both offices and meeting rooms, and male participants reveal higher percentage (43% and 32%, respectively) than female participants (38% and 28%, respectively), age and characteristic of person affect color preference in offices (Fig. 4). The study presented possible explanations of the preference of white and mentioned habituation might be one of them [25].

Previous studies have investigated chromatic, achromatic, and monochromatic color schemes in office interiors and stated that there are significant effects of color on office users' arousal, mood, performance, appraisal, and satisfaction and perceived task performance; however, these effects can differentiate according to characteristics of users, gender, and type of the task. One common discussion of these studies is the usage of white, which increases the number of errors [19] but are preferred more [25] and increases satisfaction and

Color in Schools and Offices, Fig. 4 Interior view of an office. Rengin Aslanoğlu, May 2018

Color in Offices

Color in office environments improve well-being, satisfaction, and performance.

White and blue-green office wall colors increase satisfaction and perceived job performance; workers in blue or red colored offices made less errors than white colored offices.

The effects of color schemes in office interiors can differentiate according to characteristics of users (their sensitivity towards environmental stimuli), gender, and type of the task.

Color in Schools and Offices, Fig. 5 Summary of color applications in offices. (Figure created by the authors)

perceived performance [12] in office interiors. Moreover, a recent study revealed that when white is used as a single wall color in an interior,

it cannot evoke any affective meaning, nonetheless, its pairs, separately with red and with green, can [18]. However, the previous study stated its

effect [19]; majority of users prefer white which should be investigated and clarified further because color can improve well-being, satisfaction, and performance in work environments [12, 19, 21, 27] and the preference of white might be a stereotype or a result of habituation for office interiors [25]. Van der Voordt et al. [25] mentioned color experience, mostly, unconsciously occurring in indoor environments, therefore, awareness of user might be low. Although, user preferences are important and valuable, interior architects should get over some learned and accustomed color usage in interior color schemes to overcome clichés, stereotypes, and preconceptions in order to provide more pleasant and more effective working environments in future office interiors, in working areas in public spaces, and in home-offices (Fig. 5).

Synonyms

Color in transport hubs; Color in traveling

Definition

An aspect of transportation hubs to ensure wayfinding, comfort, safety, and orientation of all users.

Role of Color Application in Transport Hubs

Traveling is an exciting but mostly challenging experience which takes an individual from their current environment to another through different

spaces. Except traveling, people are moving through transport hubs for so many reasons such as work, receiving a medical treatment, education, etc., which might cause high level of stress and intolerance. From daily routines of undergrounds to life-changing journeys to other countries, transport hubs, which are a type of these in-between spaces, have crucial importance during departures and arrivals. Although, other transport hubs such as ferry quays are being used, previous research [1–3] mostly focused on ground transport and air transport because of their wide range of usage. Transport hubs should provide safety, security, comfort, clear access, well-defined data via signage or spatial elements, orientation information, and easy wayfinding features; therefore, their architectural and interior architectural elements require more attention in terms of design, lighting, material, and especially color, which is the inevitable part of proceeding elements. Previous studies have proved that colors have a fundamental influence on perception [4–7], meaning [8, 9], and understanding [10, 11] of different aspects in interiors. Occupants are exposed to color in transport hubs on big-scale surfaces which include different combination of color qualities under effects of diverse lighting conditions (Fig. 1). In transport hubs, where color coding is essentially necessary [2], colors are fundamental visual elements to be a source of information, to ensure wayfinding and orientation, and to contribute to glare control in the context of light and material relationship. Signage's color combination effects legibility and visual search performance which are the most crucial activities in transportation hubs [12].

Schindler [13] called for exploration of light-color-material interrelationship in contexts of time and place as a result of the interview with France and Michel Cler who were mentioned as architects of the 1980s and worked with large color plans and attached social approach to their works [14]. In the light of this study, Clers' view is salient and clear that color is a game changer for public spaces in different contexts: culture, material, industry, and urban spaces [13]. Colors appear in every interior and bring their both physical and metaphorical features with them. However, in an interior such as transportation hub

Color in Transport,

Fig. 1 Manchester Piccadilly Station. Begüm Ulusoy, 23 January 2018

which provides clues and data to their occupants, colors become the source of information and play key role on interior design contexts such as safety, user satisfaction, comfort, and perception. Dalke et al. [15] recommended that interior elements should provide information for wayfinding and orientation by color and contrast, and even staff need to wear uniforms which are easy to see. Colors arouse meanings in interiors; thus, some specific colors in specific environments can cause confusion, such as Dalke et al. [2] indicated that green signs can be misunderstood as “Fire Exit.” In addition, another study revealed that, in current conditions, retail signage is more visible and attention-grapping than signage of transportation hubs. The study recommends they should be matt in order to avoid glare which is harsh and uncomfortable bright light that is caused by the light source or its’ reflection interfering with visual perception [3, 16]. Color usage in interiors of transportation hub should be balanced in order to provide less glare with high visibility while providing accurate information.

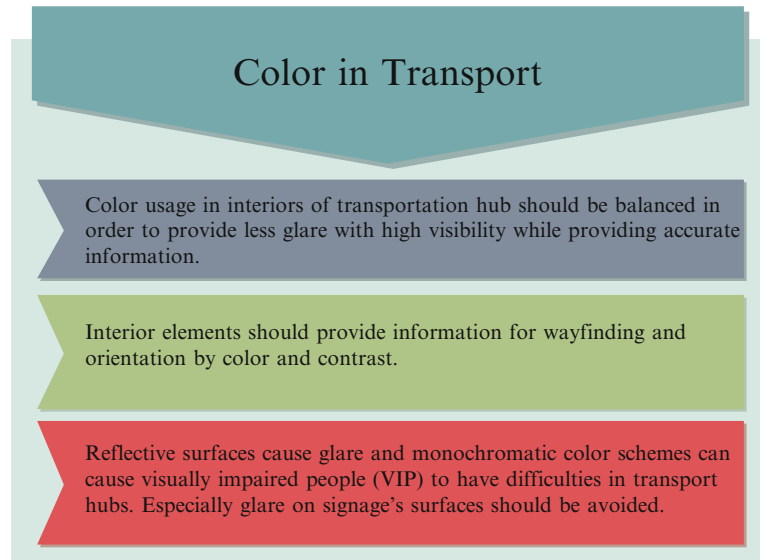

Cook et al. [17] investigated transport hubs such as train stations, bus stops, coach stops, underground, and airport; thus, they highlighted the vital importance of safety which can be maintained and supported by color, light, and design in interiors. In order to ensure comfort and safety, wayfinding and orientation have fundamental roles [2] which can be provided by color schemes in interiors. Wayfinding is a spatial problem-solving [18] which has been related to

colors [19]. Helvacioğlu and Olguntürk [19] demonstrated that colors are used as mental anchors in interiors to remember spatial features and to contribute to wayfinding. Reference points, which are mental anchors, reduce wayfinding difficulties in interiors [20]. Başkaya et al. [20] suggested colored waiting halls with other elements such as entrances, circulation systems as reference points for wayfinding, in the previous study for newcomers in an unfamiliar interior space. Colors can be used in different surfaces of interiors: walls, floors, ceilings, furniture, signage, etc. Previous study [2] pointed out light matt floor finishes in order to ensure contrast and highlighted the importance of signage’s shapes and colors rather than their texts for visually impaired people (VIP). As literature suggested, transport hubs should have a clear visual language, which should be designed and created by colors, in order to provide safety, comfort, and satisfaction for their occupants.

Previous study stated that major trends, such as wide usage of reflective surfaces or monochromatic color schemes cause visually impaired people (VIP) to have difficulties in transport hubs [3]. Glare as a major problem in such interiors for both VIPs and non-VIPs can be prevented by color and light design in interiors [1, 3]. Especially glare on signage’s surfaces should be avoided [3]; however, previous studies [2, 3] demonstrate that sparkle, i.e., attractive and extreme brightness on handrails may be useful for VIPs for their wayfinding and orientation [16]. Even though

Color in Transport,

Fig. 2 Summary of color applications in transport hubs. (Figure created by the authors)

they suggested that sparkle on handrails contributes to wayfinding and orientation of VIPs, Dalke et al. [2] stated that harsh glare on surfaces should be avoided; thus, extremely polished surfaces are not recommended. Colors which are inherently part of materials may contribute to glare control in interiors with lighting and material choices. They might be used to reduce glare in surfaces and to prevent any difficulties for the vision of occupants. In interiors, architects, interior architects, and designers aim to prevent glare; however, sparkle might be used, to the accompaniment of color, as an interior design element to clarify and highlight information which are required for wayfinding through vertical circulation elements in transport hubs' interiors.

Colors are not only fruitful and decorative but also functional interior design elements of architecture; thus, their existence and usage become more critically sensitive in public spaces such as transport hubs, shopping malls, hospitals, government offices, education buildings, etc. They are used as information sources and for wayfinding and orientation referenced by all occupants independently whether they are VIP or non-VIP. Glare should be prevented in specific surfaces such as signage, but sparkle might be used as contributing design elements on handrails for wayfinding in transport hubs' interiors. All colors provide

meanings in different contexts and in different scales of design; however, color becomes a source of information and reference point in transportation hubs' interiors, thus requires more attention and understanding (Fig. 2). In order to provide accurate wayfinding and orientation schemes and prevent glare, researchers, interior designers, and architects should focus on the relationship of colors in interiors with both other colors and indoor environment conditions, particularly lighting conditions and material properties.

Color processing in the inferior temporal cortex;
Color processing in the ventral higher visual area;
Cortical color processing

Definition

Ventral higher visual areas in the cerebral cortex play critical roles in color vision. Neural processing of color vision is studied in the inferior temporal cortex of the macaque monkey where multiple sites related to color vision are identified.

Human Studies Showing the Importance of the Ventral Higher Area in Color Vision

Damage to the human cerebral cortex can cause the loss of color vision (cerebral achromatopsia) [1]. Overlap of the damaged areas among many achromatopsia patients is the highest in a relatively small area in the ventral occipitotemporal cortex surrounding the fusiform and lingual gyri (Fig. 1). This area is located adjacent to the area where damage causes deficits in face perception (prosopagnosia). In functional-imaging experiments in human subjects with normal color vision, high activity during color perception is observed around this area [2, 3]. In addition, human subjects exposed to electrical stimulation to the color responsive sites in the ventral occipitotemporal cortex report experience of illusory color perception [4]. Together, these

findings provide converging evidence that the ventral occipitotemporal cortex is critically involved in color perception. In functional-imaging studies, multiple peaks of activity to color stimuli are observed along the anterior-posterior direction in this area [3, 5], suggesting the existence of multiple subregions in this area that are related to color vision.

Importance of the Inferior Temporal Cortex in Color Vision in the Macaque Monkey

Neural processing of color information in higher visual areas was studied in macaque monkeys. Visual signals emanating from the primary visual cortex (V1) are processed along two cortical pathways: the ventral visual pathway and the dorsal visual pathway. Along the ventral visual pathway, color information processing starts in V1, is relayed by areas V2 and V4, and finally reaches the inferior temporal (IT) cortex [6]. The IT cortex can be divided into multiple subareas. One way is to assign the anterior two-thirds of the IT cortex as area TE, and the third as area TEO. TEO has a crude retinotopic organization, while TE does not. TE neurons tend to have large receptive fields

Color Information Processing in Higher Brain Areas,

Fig. 1 Overlap of brain damages among achromatopsia patients [1]. The scale indicates the degree of overlap. Symbols indicate locations of peak activations evoked by color perception in several functional-imaging experiments. Anterior is to the top, and posterior is to the bottom. (Adapted and modified from Bouvier and Engel [1])

including the fovea. TE can be further separated into an anterior and posterior half that are named anterior inferior temporal (AIT) cortex and central inferior temporal (CIT) cortex, respectively. In this case, TEO is named posterior inferior temporal cortex (PIT).

A widely held misconception is that area V4 is the center for color vision. A large bilateral lesion of V4 causes only mild impairments in color discrimination. It is more reasonable to consider V4 an intermediate stage of the ventral visual pathway that processes information related to object vision such as color, shape, and texture, and which transmits this information to the IT cortex.

Bilateral lesions of the IT cortex cause permanent deficits in color discrimination [6, 7]. Those monkeys exhibit significant elevation of the color discrimination threshold but less severe deficits in discrimination of gray in different luminance levels were observed. Because cortical damage in lesion studies encompasses a large area within the IT cortex, it is not possible to pinpoint whether a specific subregion is most responsible for the observed impairments. Nonetheless, attempts of partial ablation of the IT cortex showed that damage in the middle temporal gyrus is responsible for the color discrimination deficits. This is consistent with the localization of color selective activities at multiple sites in this region [6]. One study also showed that a lesion restricted to area TEO does not cause a deficit in color discrimination suggesting that area TE is most important for color vision in the macaque monkey.

Functional Organization of the IT Cortex in Relation to Color Processing

There is some functional organization related to color processing in area V4 and the IT cortex. Functional magnetic resonance imaging (fMRI) studies have shown that several patchy regions of a few millimeter scale exist in V4 and in IT that are activated more strongly by chromatic stimuli than achromatic stimuli [5, 6, 8]. Electrophysiological recordings from some of these color preferential domains have shown that color-selective neurons are clustered in these regions

[8]. In the IT cortex, such color preferential domains are localized in the PIT, CIT, and AIT along the middle temporal gyrus [6]. Multiple face-selective regions exist in the IT cortex of the monkey where face-selective neurons are clustered. Color preferential domains are located adjacent and ventral to these face-selective domains [5, 6] (Fig. 2). A neuroanatomical study and an experiment combining fMRI and electrical stimulation have shown that at least some of these color preferential domains are mutually connected [9, 10]. These results suggest that color information is processed at least partially by neural pathways specialized for color information. In V4 and PIT, responses within the color-biased regions are less sensitive to stimulus orientation than those outside the color-biased regions. However, this does not imply that neurons in the color preferential domain carry only color information and do not encode information of other visual features such as shape and texture. Many color-selective IT neurons are also sensitive to shape information but there seems to exist a gradation in the separation of color and shape information in the IT cortex: neurons in the AIT cortex tend to exhibit more shape-invariant color selectivity than those in more posterior parts of the IT cortex [8, 10].

Neural Representation of Color in the IT Cortex

Color selectivity of IT neurons is analyzed by recording single-neuron activities and testing their responses to color stimuli based on the chromaticity diagram. Many color-selective neurons in both AIT and PIT are selective for particular hues and some are selective for saturation as well [8, 11, 12] (Fig. 3). There seems to exist a micro-organization of hue representation in the IT cortex: neurons preferring similar hues are arranged in a columnar fashion perpendicular to the cortical surface and the preferred hue gradually changes along the cortical surface [13]. Each color domain in the IT cortex contains neurons preferring various hues and population activities of neurons in each color domain systematically represent the entire hue circle [12]. Color selectivity of V4 and PIT neurons

Color Information Processing in Higher Brain Areas, Fig. 2 (a) Lateral view of the cerebral cortex of the macaque monkey. Visual areas along the ventral visual pathway are indicated. (b) Activation patterns to faces (dark gray) and colors (light gray) measured by fMRI in the macaque monkey [6]. In each panel, anterior is to the

right, posterior is to the left. IT, inferior temporal cortex; AIT, anterior inferior temporal cortex; CIT, central inferior temporal cortex; PIT, posterior inferior temporal cortex; TEad, dorsal subregion of the anterior TE; TEpd, dorsal subregion of the posterior TE; TEOd, dorsal part of area TEO. (b is adapted and modified from Conway [6])

Color Information Processing in Higher Brain Areas, Fig. 3 Color selectivity of six example neurons recorded from the AIT cortex tuned to different hues. Color selectivity of each neuron is represented as response contours within the region in the examined CIE-xy chromaticity

diagram (broken line). In each panel, the thicker (thinner) response contour indicates the locations where the responses were 75% (50%) of the maximum response. A dot at the center of each panel indicates a white point; adapted from Komatsu et al. [11] with modification

tend to be affected by the luminance contrast of the color stimuli, while those of AIT neurons are more invariant to the luminance contrast [12]. It appears that separation of luminance and color occurs in the AIT cortex, resulting in color representation invariant of the luminance contrast. It was also shown that color-selective neurons in the AIT cortex exhibit a significant correlation between the trial-to-trial fluctuations in neural responses and behavioral color judgments [8].

The AIT cortex has strong mutual connections with the prefrontal cortex that plays an important role in executive control of behavior. It was shown that color-selective responses of AIT neurons are affected by the ongoing task-demand such that the amplitude of the responses to color stimuli changes depending on the task demand (i.e., fine discrimination or coarse categorization of color stimuli) [8].

Unresolved Issue: Processing of Object Color

In natural and artificial environments, color vision is tightly related to the recognition of object identity or surface quality of an object. However, most studies on the role of the IT cortex in color vision have used color stimuli isolated from the visual context. Thus, our knowledge remains short of understanding the representation of object color. To address this problem, we need to know how the effects of illumination are discounted and how the optical properties of objects such as reflectance and transmittance are represented. These questions are related to a wider range of challenges such as color constancy, material perception, and intrinsic image decomposition. Some insights on these problems are available from previous studies. For example, double opponent neurons in V1 and silent suppressive surroundings of color-selective neurons in the visual cortex may be implicated in color constancy [8, 14]. In addition, it was shown that information related to material perception is mainly processed in the ventral visual pathway and that some neurons in the IT cortex are selective for surface reflectance [15]. However, more studies are needed to achieve

a comprehensive understanding of the neural processing of object color.

Color Magnitude Diagrams

Michael H. Brill
Datacolor, Lawrenceville, NJ, USA

Definition

A color-magnitude diagram is a scattergraph of astronomical objects showing the relationship between each object's absolute magnitude and its estimated surface temperature or between optical or perceptual proxies for these quantities.

Historical Antecedents

Humankind has always wanted to understand the bodies in the night sky, and one step to understanding them is to categorize them.

The first tool available to assign these categories was the human visual system – the unaided eye. Hipparchus (c. 190 BCE–c. 120 BCE) developed a scale for stars based on visual brightness, which eventually became quantified as stellar magnitude. The convention that dimmer stars have higher magnitude is a historical precedent that dates from Hipparchus [1]. However, whereas Hipparchus attached magnitude 1 to the brightest star within each constellation, Ptolemy (c. 140 AD) refined the system so that the brightest stars had magnitude 1 and the barely visible stars had magnitude 6 [1].

From the time of Galilei (1564–1642) and Kepler (1571–1630), the unaided eye became augmented by telescopes, whose main function in astronomy is to gather light from a much larger area than is available at the pupil of the eye. Telescopes were at first very limited in their light-gathering ability but later developed enough aperture so that the stars became accessible to color vision. At that point, a new categorization was possible, in which color and brightness could be conjoined.

Of course, stars have spectra that are close to black-body radiators, and such radiators have only two physical variables: intensity and temperature [2]. In perceptual terms, the color ranges from reddish through bluish through yellow and white, on a curve in the chromaticity diagram called the black-body locus. It is therefore possible to render the visible character of a star by two numbers: the brightness (magnitude) and a single variable of color (or temperature).

Diagram for Stars

At the beginning of the twentieth century, aided by the mature technology of telescopes, Danish astronomer [3] and American astronomer [4] developed the first color-magnitude diagram, called the **Hertzsprung–Russell diagram (H-R diagram)** [5–7]. Originally the diagram was based on visual estimation of magnitude and color, and it was a research tool to help characterize stellar evolution before the mechanism of nuclear fusion was understood. After about the 1930s, the H-R diagram became based on

objective measurements but was used less as a research tool and more as a way to illustrate the theoretically predicted evolution of stars through trajectories in the diagram.

The objective measurements that replaced direct human perception were as follows: A star's absolute magnitude is the attenuation (in factors $10^{-0.4}$) of the star Vega's power (as received at 10 pc viewing distance [32.6 light years]) to equal that of the star (also corrected to 10 pc).

A star's surface temperature is estimated in one of three ways: by the observed color (an old way), by a comparison of two sensor outputs such as blue and violet (a newer way), or by a model prediction of the temperature of a black-body radiator with the same radiation power per unit star-surface area (the most modern way). The third way requires independent inference of the star's radius but assumes the star has an emissivity of 1. To acknowledge the lack of compensation for the true emissivity, the temperature on an H-R diagram is called "effective temperature."

It is important to note the coordinate conventions of the H-R diagram: Temperature on a log scale [7] increases from right to left and magnitude (i.e., dimness) increases from bottom to top. Hence, dim red stars (red giants) appear near the upper right of the diagram, and bluish bright stars (such as white dwarfs) appear in the lower left. A long cluster of stars called the Main Sequence extends from the upper left to lower right. Higher-mass stars occur at the upper left of this sequence, and the Sun appears approximately in the middle. The Main Sequence is composed of stars that are currently dominated by hydrogen that is fusing into helium. According to currently accepted theory of stellar evolution, such stars will eventually migrate either to the red-giant or white-dwarf domain of the H-R diagram.

H-R diagrams are often depicted in color, either pseudo-color with a thermal code to show the temperature or coded according to star categories such as cluster membership. No matter how the measurements were obtained, the data representation for the end user returns to visual perception as the way to see the color and brightness relationships of stars.

Diagram for Galaxies

One further stage in telescope evolution occurred in 1990 when the Hubble Space Telescope was launched into orbit. The Hubble Space Telescope was able to render high-contrast images outside the Earth's atmosphere without encountering the absorption, scattering, and haze that beset Earth-bound telescopes. In digital images conveyed to earth from the Space Telescope, it was possible to see the colors, not only of stars, but of whole galaxies that are so distant as to be too dim to measure on the Earth. The color-magnitude diagram developed by Hertzsprung and Russell then evolved to accommodate galaxies. Thus was born the **galaxy color-magnitude diagram** [8]. The construction of such a diagram is similar to that of the Hertzsprung–Russell diagram, but the interpretation in terms of physical properties is not as precise.

To compute a galaxy's absolute magnitude, it is treated as a point-like object, whereupon its radiation is corrected (by the inverse-square law) to a distance of 10 pc, and the absolute magnitude is computed as the number of $10^{-0.4}$ attenuations of similarly compensated power from a reference to achieve a match.

The temperature is also the same "effective temperature" as is used in the H-R diagram. However, galaxies are visible from much farther away than individual stars, so a galaxy's recessional red shift exerts an appreciable influence on its effective temperature. Because light from farther galaxies (and greater red shift) requires more time to travel to the Earth, the galaxy color-magnitude diagram, if it were not red-shift-corrected, would depict an earlier universe at the red end of the temperature scale. However, in practice, the temperature is red-shift-corrected to be in the "rest frame" of the galaxy. In this case, the galaxies divide into two clusters: bright and reddish as opposed to dim and bluish. The existence of such clusters places strong constraints on theories of galactic formation.

Color-magnitude diagrams are not always defined in terms of fundamental physical properties such as those described above. In one embodiment, the galaxy color-magnitude diagram coordinates are defined by the log outputs of two

sensors, typically called g and r , the sensors having different spectral sensitivities: the abscissa records r (which stands in lieu of the absolute magnitude) and the ordinate records $g - r$ (which relates to the temperature). At the top of the diagram, one finds the red sequence of galaxies (elliptical galaxies), and at the bottom, one finds the blue cloud (spiral galaxies).

Definition

Humans exchange color information through the use of language, associating special words (color names) to categorical regions of color space. Color name applications in computer vision refers to algorithms that process digital images, labeling each pixel or pixel region with a given word or combination of words that matches the color name a human would give to such pixel or region.

The Problem of Labeling Image Regions by Color Name

Items belonging to different categories are easier to discriminate from each other than items belonging to the same category along a given perceptual dimension. In the case of color, the human visual system enhances the separation between certain

regions of the color space so that some colors are perceived sharply different from its neighbors, as is the case of the “bands” we see in the rainbow. These regions are then semantically categorized and assigned color names to aid communication. There are many computational applications where we need to accurately replicate these semantic categorizations to have a performance similar to humans.

The task of associating names to colors seems extremely easy for us humans, until we are presented with (semantic) categorical boundaries. This is an all too familiar situation: We ask for a yellow paint, and the shopkeeper brings us a brown-looking sample; we strongly disagree with friends about the color of our new car; or we are dumbfounded by the amount of different names given to “pink” in the paint samples’ catalogue. Providing that viewing conditions are the same, it is safe to assume that healthy individuals perceive the same colors, (This is not strictly true, and there are some astonishing but very limited exceptions such as #thredress [1].) but still, there are regions of the color space where individual observers often assign different names to the same color. In summary, there is strong agreement when naming some regions of the color space, and strong disagreement when naming others. The former are often called “focal colors,” selected by observers to best represent a given color name (e.g., “red” or “purple,” etc.), and the latter are often referred to as “categorical boundary” colors. The precise source of these individual differences remains unknown, although some authors point out the differences in the physiology (macular and lens density, pigmentation density, etc.), environmental factors (geographical differences in the environment’s statistics), linguistic and cultural factors, etc. Perhaps the most popular and influential study of basic color names across cultures and languages is that of Berlin and Kay [2], who proposed the existence of 11 “basic color terms” (in English they are “black,” “blue,” “brown,” “green,” “gray,” “orange,” “pink,” “purple,” “red,” “white,” and “yellow”). This study was later supported by others [3]. Although this and most of the research involve focal colors, some researchers have explored and mapped the

boundaries between categories trying to relate their findings to the subjacent neurophysiology [4, 5, 6]. Other factors such as viewing conditions, illumination, or the influence of surrounding areas can modify not only the perception of a given color but also category assigned.

Why Label Image Regions by Color Name?

There are many tasks we want computers to perform better than humans (e.g., driving; recognizing objects, gait, or faces; tracking; translating languages; etc.), and there are others where human performance is the milestone. In other words, we want algorithms to include the variability which is intrinsic in humans (e.g., art appreciation, image understanding, content categorization, etc.). In many such tasks, extracting higher level descriptors that provide clues to image content such as the names of the colors is fundamental. These descriptors can be later combined with image segmentation, used to select objects by color, describe the appearance of the image, generate semantic annotations, etc. A typical example is image retrieval, where the user enters a semantic description of the image (objects content, size, position, main colors, etc.), and the algorithm retrieves the most likely candidates from a large image database. Nowadays, when human-machine interaction is ubiquitous across a wide range of applications, its success ultimately requires a smooth integration with color naming: We do not want to miss possible candidates because the algorithm is constrained to a tight definition of color categories. The same applies when semantically describing the content of the picture or classifying it automatically (e.g., images of brown cars versus images of beige cars). Researchers have made use of many techniques to solve these problems.

Computational Solutions

Broadly speaking, there are two kinds of computational solutions: those based on a psychophysically based color-space partition and those

developed by applying machine learning to natural images.

Space Partitioning-Based Models

The easiest computational approach to semantically labeling colors is to create “dictionaries” of exemplary colors and names [7] or to partition the color space in regions corresponding to an arbitrary number of color names. This fairly rigid approach works reasonably well for high agreement regions (focal colors) but is not good enough to capture the large variability of human percepts.

In 1978, Kay and McDaniel went further, proposing a model based in Fuzzy set theory (which in turn is a development from standard set theory) [4] that considers four fuzzy sets (“red,” “green,” “yellow,” and “blue”). The degree to which each pixel was a member of a particular semantic category was specified as a value between zero and unity. In other words, pixels were labeled with a numerical vector corresponding to their “belonging” to these predefined semantic categories. In this framework, universal “focal” color regions can be understood as regions of maximum color-category membership functions (i.e., unity). Correspondingly, nonfocal colors have positive but nonmaximal degrees of semantic category membership and are members of more than one basic category. For the English language, these include colors such as yellow-green, reddish-purple, etc. These nonfocal, multiple membership colors capture the variability in boundary judgments reported by Berlin and Kay [2]. The membership functions of the semantic color categories were derived from physiological neural response functions for wavelength and fuzzy set operations (union and intersection). Using this model, they reinterpreted the evolutionary sequence of basic color names proposed by Berlin and Kay as the successive refinements of previously existing basic color names. A further extension was proposed by Lammens [8] who fitted Gaussian normal distributions to the 11 basic colors. This same paradigm was developed a step further by Benavente et al. [9] who incorporated arbitrary “fuzzy” membership regions (combinations of Sigmoids and Gaussians) to fit B&K’s categories to Surges and

Whitfield’s psychophysical data [10] over three lightness levels in CIELab. Mojsilovic [11] proposed a geometrical solution in CIELab that assumed a well-represented set of prototypes (foci), computing the distance between a given color and all prototypes to obtain membership values. Seaborn et al. [12] developed a model based on a Fuzzy C-Means clustering algorithm applied to psychophysical measurements by finding local minima within the group sum of squared error objective function. Menegaz et al. [13] proposed a three-dimensional Delaunay triangulation of the color space to fit their own color name data to vertices of 3D tetrahedra in CIELab space. The final 11 fuzzy categories were obtained by a series of geometrical interpolations. All the previous models were adjusted to regions of high color-category membership (maximum agreement among observers), using linear interpolation to obtain membership values outside these. A completely different approach was adopted by Parraga and Akbarinia [6] who hypothesized that linear interpolation might not be the best way to obtain categorical boundaries in CIELab and decided to psychophysically measure the performance of observers in the transitional regions. They quantified the variability and fitted the surfaces of 11 three-dimensional Gaussians (3D ellipsoids, see Fig. 1) to these boundaries. Table 1 provides a comparison of these color categorization models.

Random Initialization-Based Models

An alternative computational approach is by means of learning color names (categories) from “real-world” images. Following this line, Yendrikhovskij [17] reasoned that natural image’s hues belonging to the same color name should cluster together in a perceptually uniform space. Consequently, he applied k-means to acquire color categories from samples of pixels of natural images, using a minimum-distance criterion among members of the same color category. In a later work, probabilistic latent semantic analysis (PLSA) was applied to learn color names from a collection of images obtained from search engines [16]. PLSA was originally introduced for document analysis, and van de Weijer et al. [16]

PLSA	187	23	12.3	109	2	1.8
NICE	206	4	1.9	111	0	0

embraced this idea to model color pixels (words) in images (documents) through a combination of color names (topics). Akbarinia and Parraga [20] showed that the same set of images from [16] can be used to learn the parameters of their previously proposed ellipsoidal model, and furthermore to extend it to new color names. Figure 2 shows a comparison of some of these results.

Results obtained by some of the computational color naming models mentioned above when applied to the image in panel A. Panels B, C, D, and E correspond to PLSA [16], NICE [6] (with 11 color terms), NICE [20] (with 12 color terms), and TSMES [15] respectively.

Color names have not yet been faithfully modeled by convolutional neural networks (CNNs), mainly because deep learning requires a large dataset for its training, which currently does not exist for color names. To date, there have been few attempts to create such datasets. Cheng et al. [21] used VGG16 to learn the color names of pedestrian’s clothing items. Despite achieving a better performance in their own introduced fashion dataset, the resulting network lacks generalization to images of other environments. In summary, despite being a promising technological development, the use of CNNs to produce a more generic color naming model remains an open challenge.

Applications

Color names are actively used as a rich source of feature descriptors in a wide range of classical computer vision applications [19] that can be broadly categorized as: classification, recognition, tracking, and retrieval.

Classification: A comparison of two sets of feature descriptors, one based on the classical eleven color names and another on raw hues, suggests that adding color names increases the robustness of the well-known bag-of-words method in the task of image classification [22]. Furthermore, the fusion of standard computer vision feature descriptors, e.g., HOG, with

color names, has been reported to improve the performance of object detection [23]. Overall, it can be argued that an explicit representation of color names is an effective method for improving object detection and classification.

Recognition: A similar fusion is proved to be successful in recognition tasks as well. Color names have been reported to provide a greater balance of photometric invariance and discriminative power. These properties make color names a suitable aid for action recognition [24]. Also, it has been shown that a feature representation grounded on 16 salient color terms facilitates person recognition and reidentification in video surveillance datasets [25].

Tracking: When it comes to visual tracking, it is well established that chromatic information provides a significant aid to the task; however, it is computationally demanding. This complexity can be overcome by using color names, which have been shown to have the efficiency of raw chromatic information, while being computationally more affordable [26].

Retrieval: color names are one of the first attributes chosen by humans when describing an object. With this in mind, Zheng et al. [27] supplemented a SIFT feature with basic color names, boosting the task of image retrieval by reducing false positives and improving query time. In order to reduce the semantic gap in algorithms of image retrieval, Liu et al. [28] proposed to associate each region of an image with a color name. This technique better meets user expectations when they use color names to describe their query.

A recent online survey investigated which color names are commonly used without restrictions of choice [29]. The results suggest that average individuals use more than 11 color names. Based on these results, Yu et al. [18] demonstrated that including a larger number of color names (28), instead of the traditional 11, increases the discriminative power of the color descriptors in the tasks discussed above. Griffin and Mylonas [30] used the data from [29] as a color metric to geometrically categorize the color space. Interestingly, the number of emerging regions within the RGB cube corresponds well to the optimum names used in [18].

During the past decade, the state of the art in the above applications has shifted from classical computer vision algorithms to deep learning approaches where the optimization of the network's parameters (millions of them) is often best achieved in an end-to-end training procedure. In other words, the features learnt by these networks are mainly data-driven. In most cases, imposing tailor-made features is likely to complicate the algorithms and impoverish the results. For this reason, incorporating color names to otherwise "pure" deep-learning algorithms has been little explored.

Outline for Future Research

Although much has been done in the past, there is still large room for improvement before achieving human-like performance in color-naming applications. The main problem is that humans are "noisy" when it comes to categorizing objects by color, and this noise has both perceptual and cognitive sources. Another great limitation has to do with statically assigning a color term to a given RGB value. In this paradigm, an arbitrary RGB value will always have the same color name regardless of its context and surrounding. Very few works (see [20]) have tried to address this point by dynamically adjusting the categorical regions to the image context. Given that human color perception is strongly influenced by local and global context, this dynamic color naming approach seems promising. On the other hand, modern CNN models also promise to advance the field by expanding the number of categories and learning some of the cultural variability; however, now there is a crippling lack of reliable datasets, although this is likely to improve in the future.

As a corollary, it is worth mentioning that the rewards for creating a robust color-naming paradigm are enormous, since many important fields (e.g., social robotics, image understanding, etc.) rely on it. There are also important advances to be made in helping visually impaired people appreciate and navigate a colorful world.

Definition

Color order systems can be defined in three ways:

- (a) A system for categorizing colors. An arrangement of perceived colors, color stimuli, or material color samples according to certain rules.
- (b) A subset of the world of color according to three attributes that constitute the coordinates of the color system.
- (c) A rational plan for ordering and specifying all object colors by a set of material standards.

Color Systems: Review and Evaluation

The aim of introducing order into the vast set of colors that most humans are able to distinguish has existed since ancient times. Among the people who have proposed some kind of color order systems, there are famous philosophers,

architects, artists, scientists, and writers, most of whom are included in a recent book about the pioneers of color science [1]. We can mention Aristotle (c.350 BC), ► [Avicenna](#) (c.1000), Leon B. Alberti (1435), Leonardo da Vinci (1516), ► [Isaac Newton](#) (1704), Johann Heinrich Lambert (1772), and ► [Johann W. Goethe](#) (1810). In the twentieth century, other scientists and theorists, such as ► [Albert H. Munsell](#) (1905, 1907, 1915), ► [Wilhelm Ostwald](#) (1916, 1917), Arthur Pope (1922, 1929, 1949), Cándido Villalobos and Julio Villalobos-Domínguez (1947), Antal Nemcsics (1975), Harald Küppers (1978), and Frans Gerritsen (1987), just to mention a few, have been outstanding in formulating and building color order systems. This endeavor has also been pursued by organizations such as the Commission Internationale de l'Eclairage (1931, 1976), the Optical Society of America (1947–1977), the Swedish Standards Institution (1979), and others.

A color order system seeks to include samples of all colors in a spatial model, giving a specific position to each color and proposing some kind of logic that determines the whole organization. These models have very diverse shapes, according to the different authors and along times: linear scales, two-dimensional diagrams, chromatic circles, color triangles, and color solids of various shapes. Within this last type, different solutions have been introduced: cones, pyramids, double cones, double pyramids, spheres, and more or less irregular solids.

Old Linear Organizations and Diagrams

The most ancient color organizations are often simple lists of color names, linear scales – generally expressed in verbal form, without graphic representations – or two-dimensional diagrams in the form of color schemes, triangles or circles. Among the first group, two can be mentioned: the five basic colors of the old Chinese philosophy (grue [qing, a conflation of blue and green], red, yellow, white, and black), related to five elements (wood, fire, earth, metal, and water, respectively) and to the five metaphysical localizations (east,

south, center, west, and north, respectively), and the color scale of Aristotle (384 BC–322 BC), with white and black at the ends, and a series of intermediate chromatic colors linearly arranged between these two extremes of lightness and darkness.

By the turn of the first millennium and during the next two centuries, there were some developments stemming on the Aristotelic school in Western Asia. ► **Avicenna** (980–1037), the Persian philosopher and scientist, expanded the linear sequence by establishing three possible paths from white to black. Another Persian polymath, ► **Nasir al-Din al-Tusi** (1201–1274) described a system of color mixture with five paths from white to black. By interpreting their texts and rendering them graphically, Kirchner and Bagheri obtained schemes that can be considered intermediate steps between linear arrangements and two-dimensional diagrams [2]. In parallel, a similar description is found in Europe around 1230 in the text *De colore* by the English scholar Robert Grosseteste (circa 1175–1253).

A verbal ordering of colors, which some later authors reconstructed as a chromatic circle or a square, and even as a double cone, a double pyramid, or a sphere [3], is found in the book *On painting* by the Italian architect Leon Battista Alberti (1404–1472).

A great deal of the *Treatise on painting* by Leonardo da Vinci (1452–1519), compiled after his death from his notebooks, is dedicated to insights about color. For the arrangement of colors, he proposed a simple scheme based on the oppositions black-white, blue-yellow, and green-red.

The Belgian Jesuit Franciscus Aguilonius [1] (1567–1617) published his *Opticorum libri sex* in 1613 in Antwerp, and the German Jesuit Athanasius Kircher (1602–1680) published his *Ars magna lucis et umbrae* in 1646 in Rome. Both texts include diagrams with a primary linear arrangement of colors connected by arcs that indicate the results of their mixtures (Fig. 1).

Aron Sigfrid Forsius [1] (1550–1624), a Finnish-born clergyman, cartographer, and astronomer who worked in Sweden, wrote a

Color Order Systems, Fig. 1 Object color diagrams of the seventeenth century

manuscript in 1611 where the first-known drawing of a ► **color circle** appears. Forsius' circle presents the following sequence: white, yellow, red, brown, black, green, blue, and gray, closing again in white (Fig. 1a). Forsius characterized this circle as "ancient" and drew an alternative for the arrangement of colors. Various theorists have interpreted this second diagram as a sphere, but this is controversial (Fig. 1b). If this can be demonstrated, it would be the first three-dimensional system in the history of color. Since Forsius did not write the word "sphere" in the accompanying text, and the drawing is schematic and not well fitted to the representation of a sphere in vertical projection or in perspective, it is difficult to accept this. In addition, the diagram has two misplaced colors, if we want to understand it as a logical natural color system: Blue and green should exchange places [4]. This is mere speculation, but since this diagram has led to a lot of contemporary discussions, interpretations, and misunderstandings, had it been more widely known in published form during Forsius time, instead of being kept as a manuscript in the Stockholm library, it is likely that its influence could have led other scholars to conceive a true color sphere in the seventeenth century, even through the way of misinterpreting Forsius diagram.

In 1629 Robert Fludd (1574–1637) published a circular diagram. However, rather than a two-dimensional circle, it is a color ring (*colorum annulus*), that is, a round sequence that includes black (*niger*) and white (*albus*) in the steps. It is a way of connecting the extremes of the Aristotelian linear scale by bending it.

In 1685, Johannes Zahn (1641–1701) published the first known color diagram in the form of a triangle (Fig. 1). But, again, it is not a triangle of full hues (as we understand it today), nor is it a triangular surface. It is a scheme of color relationships and mixtures, similar to Aguilonius' diagram, but using straight lines (instead of arcs) to connect the colors. That is, the colors are placed at the intersections, and they do not fill the surface. At the base of the triangle, we find a scale of three colors – yellow (*flavus*), red (*rubeus*), blue (*caeruleus*) – between white (*albus*) and black (*niger*). The mixture of white and black makes

gray (*cinereus*), yellow and red make orange or golden (*aureus*), red and blue make purple (*purpureus*), and yellow and blue make green (*viridis*). There are the other mixtures as well.

These linear, circular, or triangular diagrams include black and white in their sequences and are not truly two-dimensional color spaces, in the modern sense.

Modern Two-Dimensional Color Arrangements

The first modern ► **color circle** appeared in 1704. ► **Sir Isaac Newton** (1642–1727) discriminated seven colors in the spectrum produced by the dispersion of light through a prism, and arranged them in the perimeter of a circle divided into seven portions, with the center occupied by the white light. The fact that Newton included seven colors (5 with a larger span interval and 2 with a shorter one) is due to the parallelism he made with the seven musical tones and half-tones of the diatonic scale. The circle is a representation of a mixture of spectral lights that blend in white at the center. In modern terms, it is an additive color mixture. Different from any previous circular representation, here the idea is that color mixtures fill out all the surface progressively, from the outer spectral sequence towards the white center (Fig. 2, left). However, the difference between additive and subtractive mixture was not clear at the time of Newton. It began to be understood only during the nineteenth century. Newton's circle is the direct antecedent, with some intermediate steps, of the development of the ► **CIE 1931** chromaticity diagram.

In 1708, very close to the publication date of Newton's *Optics*, a book on miniature painting was published, which at the end included two painted color circles. The authorship of these circles is uncertain; various scholars attribute them to Claude Boutet. The first circle has seven colors (like Newton), but the most interesting one is the second circle, which contains 12 hues, arranged in triads. This is the older known representation of the traditional color wheel used by painters until today, and also the first published color circle that

Color Order Systems, Fig. 2 Left: Newton's circle. Right: Mayer's triangle

represents a trichromatic mixture, with a triad of yellow, red, and blue, inscribed in an equilateral triangle, opposed to another triangle with green, orange, and purple. Other six intermediate hues complete the 12 hues circle. This circle with subtractive mixtures of red, yellow, and blue is a truly modern two-dimensional color diagram and is kept practically without changes until nowadays. We can see it adopted again by Moses Harris (1770), ► [Johann W. Goethe](#) (1810), ► [Philip Otto Runge](#) (1810), Charles Hayter (1826), George Field (1841), ► [Michel-Eugène Chevreul](#) (1864), Arthur Pope (1922), ► [Johannes Itten](#) (1961), and many others [1].

The first modern color triangle, with three chromatic hues, and with colors filling all the surface, was proposed in 1758 by ► [Tobias Mayer](#) (1723–1762), in a public lecture delivered in Göttingen, and published after Mayer's death by Georg Lichtenberg, in 1775. The triangle has red, yellow, and blue as ► [primary colors](#), and Mayer developed a color notation system and a theory of mixtures by quantifying and combining the amounts of each primary in terms of 12 steps. The method and theoretical formulas look as if they were following additive principles, but we have to remember that the difference between additive light mixture and subtractive pigmentary mixture was not well understood at that time, and

thus, the system is somehow confusing in this sense. The colored representation of the triangle was produced with pigments (Fig. 2, right), and a dull gray or brown color is obtained by the mixture of the three primaries, instead of white that would result from an additive mixture, as in the case of Newton.

Mayer's unpublished papers were collected posthumously in a book edited by Georg Lichtenberg, including a hand-colored version of the triangle. Even when Mayer did not produce a drawing of a three-dimensional model, it can be interpreted from his formulation. In a commentary to the publication, Lichtenberg describes a prism that can be derived from Mayer conception and states that the result “can be reached more elegantly with two identical pyramids having a common base.” This description has been rendered graphically by Heiwing Lang [5].

Two Important Three-Dimensional Systems Before the Twentieth Century

Around 1760, ► [Johann Heinrich Lambert](#) (1728–1777) was aware of reports of Mayer's triangular system published in Göttingen. Lambert devised a color pyramid, which was published in 1772. This was the first color solid

expressly developed and drawn as such by its author. The pyramid has a triangle with scarlet (equivalent to primary red), amber (equivalent to primary yellow), and blue at its base, from whose mixtures Lambert was able to obtain black in the center of the triangle at the base. Hence, this is an arrangement of subtractive mixture of pigments. By placing white in the upper vortex, the system is completed. Along the vertical axis, we find successive triangles that become lighter and lighter from the base to the top of the pyramid.

The German painter ► [Philip Otto Runge](#) (1777–1810) built a color sphere that is considered the ancestor of most of the twentieth-century color systems and could be termed “modern” for this. Runge’s sphere, published in 1810, is the significant result of a sustained evolutionary process initiated in the Renaissance. The chromatic circle, at the equator of the sphere, is arranged on the basis of the red-yellow-blue triad of ► [primary colors](#), plus the green-orange-violet triad of secondary colors, as in Boutet and Goethe’s circles.

Classification of Color Order Systems

Color systems can be categorized into two large groups: color stimulus systems and color perception systems. Color stimulus systems are established in the twentieth and twenty-first centuries. Their developers are almost without exception physicists and information specialists. They are based on systematizing radiation energy of different wavelengths creating the experience of different colors. Some of these systems are registered as industrial international standards. Their detailed description may be found in chapters of the Encyclopedia dealing with the measurement of color and computerized display of color.

The roots of the establishment of color perception systems appear in the distant past. Their creators belong to different professions and include among others, painter artists, architects, writers, poets, philosophers, doctors, priests, bishops, chemists, botanists, and many other crafts, representing the diversified world of colors.

The established multitude of perception-based color order systems can be categorized into eight groups in terms of aims, classification methods, and definition of color patterns by color notation. Irrespective of their categorization, they possess numerous identical attributes.

Every perception-based color system possesses a color atlas containing a set of color samples. Early on, colors were placed on plane surfaces, within regions represented by a triangle, square, or circle. Later, in the eighteenth century, it turned out that the multitude of colors could only be arranged within a three-dimensional space. With the exception of a few systems (Munsell, and Coloroid, among them), colors were arranged on the surface of, or within, regular bodies. The most frequently applied bodies were the following: a triangle-based pyramid (Lambert and Mayer), a circle-based double cone (Ostwald [6]), a square-based double cone (Höfler), a circle-based truncated cone (Baumann-Prase), a cube (Hickethier), a sphere (Runge), a half-sphere (Chevreul), a body of rotation consisting of cones (Wilson), a circle-based cylinder (Frieling), and a body constructed of cube-octahedrons (OSA).

The irregular shapes of the color bodies of Munsell and Coloroid systems are the result of the fact that, as opposed to other color systems, they take into account the magnitude of chromatic strength and lightness of colors of different hues, as well as practical issues pertaining to the production of colors of high saturation and high luminance for some hues.

All perception-based color order systems are discontinuous, the single exception being the Coloroid system. They contain only a definite number of colors from the color space. In most of the systems, the letter or number notating the color indicates the location of the color in the color atlas. In most of the systems, the color notation gives the additive or subtractive components for mixing the given color. In some systems, it defines a particular color perception. In the case of some color systems (e.g., Munsell, NCS), the color coordinates of the CIEXYZ color system are provided for a definite number of their colors. This allows the calculation of CIE coordinates –

by interpolations with different degrees of accuracy – also for colors not presented in the color atlas. A direct transformation relation exists only between Coloroid and CIEXYZ which enables defining with equal accuracy in both systems all colors distinguishable by the human eye, that is, more than a million colors.

Review List of Ancient and Modern Color Order Systems

Systems of Color Stimuli

One criterion for classifying systems of color stimuli is whether they depend on some particular device to produce them or not. In a device-dependent color system, the resultant color depends on the equipment used and its calibration. The same RGB stimulus generated in a computer display (for instance, $R = 255$, $G = 0$, $B = 255$, which yields a magenta) will give different results depending on the type of display used (CRT, LCD, LED), its brand, the brightness and contrast setup, etc. In a device independent color system, on the other hand, the coordinates that specify a color will indicate the same color, independently of the medium by which it is produced.

Color Systems Used Today, Recommended for Art and Design

Munsell Color System

The foundations for the most up-to-date idea of color systems were first laid down by ► [Munsell](#), who published his *Book of color* [7] and the pertinent color sample collection in 1915 for the first time. This system was further developed in 1943 and correlated to the ► [CIE 1931](#) colorimetry system. In 1956, it was extended to include very dark colors. Later, the Munsell Color Company was founded for re-editing at regular intervals, in the original quality, the color collection of the system. Since 1979, it is also published in Japan under the title *Chroma Cosmos 5000*.

The Munsell system is still one of the most popular color systems. Its codes are up to this day the most common color identification numbers in the international literature. Colors are identified by three kinds of perceptual data: hue H , value V (lightness), and chroma C . These data are the three coordinates of the Munsell color solid, characterized by cylindrical coordinates and corresponding to the three characteristics of visual perception.

The hue scale of the Munsell system is divided into 100 perceptually equal parts according to 10 shades each, of the following five reference and five mixed colors: red (R), yellow-red (YR), yellow (Y), green-yellow (GY), green (G), blue-green (BG), blue (B), purple-blue (PB), purple (P), and red-purple (RP) (Fig. 3).

The vertical axis of the Munsell color solid accommodates gray (neutral, N) colors. The achromatic scale is divided in a perceptually equidistant manner from 0 to 10. Munsell value (lightness) of a perfectly absorbing surface (ideal black) is 0, while that of a perfectly and diffusely reflecting surface (ideal white) is 10. Munsell chroma increases with the distance from the achromatic axis (Fig. 4). In the Munsell system, colors are marked as $H\ V/C$, for example, 10RP 5/6. The shape of the Munsell color solid is shown in Fig. 5. The relationship between the Munsell color system and the CIE colorimetric system has been tabulated.

Natural Color System (NCS)

One of the latest ideas on color systematization relies on the Hering-Johansson theory, materialized as the color atlas by Hesselgren issued in 1953. Based on this atlas, in 1972 Hård, Sivik, and Tonnquist developed the Natural Color System (NCS), which was adopted as a Swedish standard in 1979.

The authors of this system started from ► [Ewald Hering's](#) idea about six elementary color perceptions, that is, white (W), black (S), yellow (Y), red (R), blue (B), and green (G). In the NCS, every color is described by the degree of its similarity to the six elementary colors [8].

A color cannot be similar to more than two hues. Yellow and blue exclude each other, and so do red and green. The sum of the color variables defines the NCS chromaticness (c) of the perceived color and their ratio its hue (Φ).

In the NCS, colors are marked as $sc\text{-}\Phi$, for instance, 2040-G40Y, where s is blackness, c is chromaticness (a magnitude associated with saturation), and Φ is the hue of the color. In the color notation, the s and c values – both of two digits – are written without space and separated from Φ by a hyphen. The hue of the color in the example above is intermediate between green (G) and yellow (Y) in a ratio of 40 to 60.

The geometric form that the NCS assumes is a regular symmetric double cone with white and black at the vertices, while the other four preferential hues are on the circle of full colors, at corners of a square touching this circle (Figs. 6, 7, and 8). This color solid is of the same shape as that of the Ostwald system [6]. Also, the basic principle of some variables was adopted from the Ostwald system, but with a modified definition and scale. Similarities and differences between the CIE and NCS color spaces have been tabulated, but no exact mathematical correlations were established.

The significance of the NCS is that it operates with a tetrachromatic color description as a possible way of visual color description.

Color Order Systems, Fig. 3 Hue circle of the Munsell system

Coloroid System

Coloroid is a system of surface colors illuminated by daylight and sensed by normal color vision observers, built on harmonic color differences according to sensation, that well approximates aesthetic uniformness. Coloroid has a direct transformation relation with the CIEXYZ system. It was elaborated at the Budapest Polytechnic University by Nemcsics and first published in 1975. Since 1982 it has been a Hungarian technical

directive, and it became a Hungarian standard in 2002 [9–11].

Coloroid coordinates are semipolar coordinates, representing the members of the population of colors placed inside a cylinder, to be used for the explicit definition of color points, namely, the angular coordinate representing numerically the hue of the color (A), the radial coordinate representing numerically the saturation of the color (T), and the vertical axial coordinate representing the luminosity of the color (V).

Color Order Systems, Fig. 6 Hue circle of the Natural Color System

Absolute white (W) is placed on the upper limit point of the axis of the color space. It is the color of a surface illuminated by the CIE D65 illuminant, with perfectly scattered reflection, having both Coloroid luminosity value and Yw color component value of 100. Absolute black (S) is placed on the lower limit point of the axis of the color space. It is the color of a surface illuminated by the CIE D65 illuminant, perfectly light absorbing ($\beta = 0$ luminance factor), having both

Coloroid luminosity value and Ys color component value of 0.

The Coloroid limit colors are the most saturated colors that can be drawn onto the surface of the cylinder comprising the Coloroid space, located along a closed curve. The Coloroid basic colors are 48 different limit colors characterized with integer numbers, being located at approximately identical number of harmony intervals to each other. The Coloroid basic colors are recorded

Color Order Systems, Fig. 7 Axial section of the NCS solid, displaying the Y10R hue with the variation of darkness and chromaticness

in the CIE 1931 diagram by the jangle. The jangle is the angle of the half line originated from the D65 point of the CIE 1931 chromaticity diagram to the x axis.

The Coloroid color planes are the half planes delimited by the achromatic axis of the color space, having the same hue and dominant

wavelength. In each color plane, colors are enclosed by the neutral axis and two delimiting curves. The shape of surfaces enclosed by delimiting curves is different for each hue and depends on the luminosity of the color located on one apex of the color plane. Along the vertical lines of the nets drawn on the color planes,

Color Order Systems,**Fig. 8** Schematic representation of the solid of the Natural Color System

Coloroid saturation values are identical; along their horizontal lines, Coloroid luminosity values are identical. Colors implemented with various means or colors created in nature, belonging to individual color planes, are enclosed by internal delimiting curves.

The Coloroid basic hues are the hues belonging to Coloroid basic colors. Similarly to basic colors, there are 48 Coloroid basic hues. In color planes A10 to A16 yellow, in color planes A20 to A26 orange, in color planes A30 to A35 red, in color planes A40 to A46 purple and violet, in color planes A50 to A56 blue, in color planes A60 to A66 cold green, in color planes A70 to A76 warm green hued colors exist.

Coloroid saturation is a characteristic feature of the surface color quantifying its saturation, that is, its distance from the color of the same Coloroid achromatic luminosity measured on a scale that is aesthetically near to uniform. Its denotation is T. The saturation of the limit colors is equal to 100. The saturation of absolute white, absolute black, and gray is equal to 0. In the Coloroid space, colors of identical saturation are located equidistant to the achromatic axis, on a coaxial cylinder.

Coloroid lightness is a characteristic feature of the surface color denoting the distance measured from absolute black on an aesthetically near-uniformly graduated scale. Its denotation is

V. The lightness of absolute black is equal to 0. The lightness of absolute white is 100. In the Coloroid space, colors of identical lightness are located in planes perpendicular to the achromatic axis. Numerical values of the Coloroid lightness of a surface color are determined by the expression $V = Y^{1/2}$.

Coloroid hue is a characteristic feature of the surface color denoting its hue on a scale distributed into 48 sections on an aesthetically near-uniformly graduated scale. Its denotation is A. The Coloroid hue of the surface color is a function of the dominant wavelength. In a Coloroid space, surface colors having identical hues lie in the Coloroid color planes.

The color notation in the Coloroid system is expressed by hue (A)–saturation (T)–lightness (V), for instance, 13–22–56 (Figs. 9, 10, and 11).

Küppers' Atlas and Rhombohedric Color System

The German engineer Harald Küppers published an atlas specifically useful for the graphic arts and the printing industry, containing more than 5,500 nuances [12]. The color samples of this atlas were produced by the technique of four-color printing, mixing the four transparent dyes, yellow,

Color Order Systems, Fig. 9 Hue circle of the Coloroid system

magenta, cyan, and black, with the concurrence of the white background of the paper.

The gradations of the mixtures are expressed in percentages directly equivalent to the proportion of surface covered by each dye, so that this notation not only is useful to designate the different nuances but also as a formula to produce the colors. The variation is made by differences of 10% between an individual sample and the next one and between a chart of colors and the next one.

The published color charts are divided into five series; three of them are said to be of achromatic mixture because of the intervention of

black, and the other two are considered of chromatic mixture due to the exclusive intervention of yellow, magenta, and cyan. In the first three series, black is added to a mixture of two chromatic dyes – made in 10% steps of variation and held constant for the whole series – in 10% steps of variation from one chart to another. In the fourth series, yellow is added in successive charts to a fixed mixture of two chromatic dyes (magenta and cyan). Series 1–4 have 11 charts, with 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 99% of the dye being added to the fixed binary mixture. The fifth series has two additional charts: one with

Coloroid színatlasz

A54

Color Order Systems, Fig. 10 Axial section of the coloroid solid, displaying one hue with the variation of lightness and saturation

yellow-cyan mixtures and 99% of magenta and the other with yellow-magenta mixtures and 99% of cyan.

Küppers also represented his system as a three-dimensional space, either as a cube (Fig. 12) or with a rhombohedral shape, constituted by an

Color Order Systems,

Fig. 11 Color solid of the coloroid system

upper tetrahedron, a central octahedron, and a lower tetrahedron (Fig. 13). In the rhombohedral model, white is placed in the upper vertex of the upper tetrahedron, in whose base the three subtractive printing primaries are placed: yellow, magenta, and cyan. This base is also one of the faces of the central octahedron. The lower triangular face of the octahedron holds the three colors resulting from the mixture of the subtractive primaries in pairs: green (yellow with cyan), red (yellow with magenta), and blue (cyan with magenta). This face is, in turn, shared with the lower tetrahedron, in whose lower vertex black is placed.

Additional Studies, Classifications, and Evaluations of Color Order Systems

The bibliography about historical, comparative, or classificatory analysis of color order systems is extensive. In addition to the already stated references, articles by Spillmann [13], Robertson [14], Sivik [15], and Tonnquist [16] offer significant information. The International Color Association devoted a whole congress to the theme of color order systems in 1983 [17] and had a study group on this subject from 1978 to 1990, chaired successively by ► Günter Wyszecki, ► Fred

Billmeyer, ► James Bartleson, and William N. Hale (see [18]).

Especially interesting is the analysis made by Billmeyer [19], which deals with the history and the principles of various systems, establishes comparisons and differences, and offers data about the attempts of conversion among the notations of various systems. William Hale [20] discussed the uses of color order systems, including those that have a relevant theoretical or scientific basis as well as those more pragmatic and with a specific commercial purpose. Tonnquist [21] offered another criterion to classify color order systems. He divided them into (a) *physical*, those that have actual samples as reference and that only exist in terms of an atlas or a color chart; (b) *psychophysical*, those whose definition is given by means of valences for a set of points in a color space, and whose definition is only valid to a combination of observer, illuminant, and measuring system, as, for instance, the CIE system; and (c) *perceptual*, those defined in terms of elementary color percepts, mental references of certain basic colors which serve to describe all the remaining colors, as, for instance, the NCS.

Some countries have adopted certain color systems as national standards. During the 6th Congress of the International Color Association, a specific discussion about the question if any

Color Order Systems, Fig. 12 Harald Küppers' model atlas in a cubic shape, and a page from it

particular system is better than the others took place ([22], vol. I, pp. 163–172). The conclusion was that there is no particular system that is best for all the applications, which may cover fields so different as color education, artistic practice in various disciplines, professional practice in diverse branches of design (architectural, graphic, industrial, textile, landscape design), specification of color in materials so dissimilar as paper,

fabrics, leather, plastics, metals or in complex industries such as the automotive, the food industry, color reproduction in TV, video, and computer displays; some systems are more useful than others for certain specific problems. In the 7th Congress of the AIC, a round table on color order systems was also organized ([23], vol. A, pp. 173–174) in which there was a consensus on some points, among them (a) that physical color

Color Order Systems, Fig. 13 Küppers' rhombohedric model

samples, although useful, are not essential to a color system and (b) that broadly, the systems can be divided into two types: systems of color appearance (a typical example would be the NCS) and systems of color stimuli (an example would be the CIE system). All systems developed so far are applicable to trichromatic observers. Monochromatic, dichromatic, and tetrachromatic observers have as yet no systems applicable to them.

The interested reader can look for additional information on description, analysis, and comparison of color order systems in Caivano [24], Stromer and Baumann [25], Silvestrini, Fischer and Stromer [26], Stromer [27], Kuehni [28], Kuehni and Schwarz [29], and Spillmann [30], among other sources. There is also an excellent website devoted to this subject: <http://www.colorsystem.com>.

Punctuated Evolution of Color Order Systems

We can consider that the development of color order systems along history follows an

evolutionary path. However, instead of being a matter of gradual transformation, it is a kind of punctuated evolution, with steps or jumps where the changes appear.

With regard to spatial or geometrical aspects, linear arrangements (Aristotle and followers) are seen first. In the next step, connections are added to the linear sequence until it is closed in a circumference (Fludd) or a triangle (Zahn), but with empty spaces inside. Next, the circle was filled in (Newton), and achromatic colors disappeared from the border and were enclosed. This was a revolutionary step in the eighteenth century. While it took nearly 2000 years to close the circle, and near 100 years to fill it, it took just a little more than 50 years for this surface to be transformed into a three-dimensional space (Mayer, Lambert). These two last important changes took place within the eighteenth century, where the modern conception of color systems was developed (Fig. 14).

During the nineteenth and twentieth centuries, the 3D models suffered improvements: Additive and subtractive processes were separated, and the shapes started being divided into models with one vertex and models with two vertices.

Color Order Systems, Fig. 14 Scheme of the evolution of color order systems

Some of them began to appear with the chromatic circle tilted (pure yellow closer to white, pure violet, or purple closer to black), and thus, this surface became more elliptical than circular. Already in the twentieth century, some models, instead of having a convex volume (spheres, cones, double cones, pyramids, double pyramids), started to have more complex shapes, with positive and negative curvatures, both in the chromatic surface of full hues and in the outer surface of the model.

This process of punctuated transformation by means of more or less small steps or divisions will undoubtedly continue. What will be the next steps? We can think of at least two ways:

1) Adding one or two more dimensions to the 3D shapes, in order to encompass not only the three classical color variables (e.g., hue, lightness, saturation) but also other variables of **appearance**, such as gloss and transparency.

2) Taking into account that human color vision will probably evolve towards a tetrachromatic system (cases have already been found of women with **tetrachromatic vision**), and thus color order systems should reflect this tendency ... in a somehow distant future, however.

Color Perception and Environmentally Based Impairments

Galina V. Paramei

Department of Psychology, Liverpool Hope University, Liverpool, UK

Synonyms

Acquired color vision impairment; Acquired color vision loss; Dyschromatopsia

Definition

Decreased discrimination of colors caused by adverse environment, such as long-term occupational exposure to or consumption of drugs, substances, and food containing neurotoxic chemicals.

Types of Neurotoxic Substances Causing Dyschromatopsias

Color vision early manifests adverse effects of exposure to an environment that contains neurotoxic substances [1–3]. The acquired color vision impairments, or dyschromatopsias, can be very subtle (subclinical) but also may vary considerably in severity, increasing or decreasing as long as the responsible agent persists, and can become irreversible under long-term exposure and/or agent dose.

There are several scenarios of exposure to hazardous chemical agents in the environment:

- (i) Long-term occupational exposure to certain substances (e.g., neurotoxic metals, organic solvents, carbon disulfide, etc.)
- (ii) Self-administered chronic consumption of substances containing neurotoxic chemicals (e.g., alcohol, tobacco).
- (iii) Side effects from pharmacological treatment of medical conditions (e.g., cardiovascular, antiepileptic, or antituberculosis drugs).
- (iv) Consumption of food contaminated through the food chain by neurotoxic elements (e.g., mercury).

General Characteristics of Neurotoxin-Induced Color Vision Impairments

Acquired color vision defects, unlike congenital ones, are noticeable to the observer: recently affected subjects name the stimuli as they see them – in contrast to subjects with congenital color vision defects where there is compensatory adaption of their color naming to that of normal trichromats. Acquired

dyschromatopsia may not be identical in the two eyes, which requires testing the two eyes separately.

Neurotoxic substances can affect one or more loci in the color vision system. At the pre-receptor level, hazardous chemicals can accelerate yellowing of the crystalline lens which results in an increase in absorption of short-wavelength light and hence decreased discrimination of blue colors. In the retina, the main mechanism of color vision loss is selective damage to specific photoreceptor classes, short-wavelength (S-), middle-wavelength (M-), or long-wavelength (L-) cones (► [Cone fundamentals](#)). Most vulnerable among these are the S-cones, damage of which is manifested by blue color vision defects [3]. Post-receptoral processing can also be disrupted – at the level of ganglion cells, optic nerve, optic radiation, or visual cortex – causing color vision impairment. Often the damage is nonselective, i.e., patterns of color discrimination loss are not always specific to one of the color subsystems and differ from those in congenital abnormalities.

Classification of Acquired Dyschromatopsias

The wide variation in acquired color vision defects, according to Verriest [4], can be classified in four major types, I, II, III, and a nonspecific defect. The first two types are associated with impaired color discrimination along the red-green axis in perceptual color space (Color Vision, Opponent Theory), much like the patterns found in congenital red-green deficiency, i.e., both involve mild to severe confusion of reds and greens. Type I is protan-like and reveals little or no loss of blue-yellow discrimination (► [Protanopia](#)); Type II is deutan-like and is manifested by concomitant mild loss of discrimination between blues and yellows (► [Deutanopia](#)). Type III, tritan-like, is manifested by mild to moderate blue-green and yellow-violet confusions, with a lesser or absent loss of red-green discrimination (► [Tritanopia](#)). Both color systems appear to be selectively susceptible to damage by various types of neurotoxins.

According to Köllner's rule [1], impairment of blue-yellow discrimination – the range most frequently affected by exposure to hazardous chemicals – suggests toxic retinopathy, i.e., a more external retinal dysfunction; by contrast, a preponderance of red-green loss is associated with pathology in the optic nerve; finally, complex color vision loss, blue-yellow and red-green, suggests a more advanced stage with a damage to both the retina and the neuro-optic pathway. However, numerous exceptions to Köllner's rule instruct one to be cautious about making a clear-cut attribution of blue-yellow loss to damage at a retinal level and of red-green loss to damage at a neural level.

Tests of Color Vision for Assessing Acquired Dyschromatopsias

In epidemiological studies, three color arrangement tests are predominantly used: the Farnsworth-Munsell 100 Hue (FM100) test, the Farnsworth Dichotomous panel D-15 test, and the Lanthony Desaturated Panel D-15d (► [Color Vision Testing](#)). In the arrangement tests, caps sample a color circle (► [Color Circle](#)) at even intervals. In field studies, the two shorter tests, the D-15 and the D-15d, are predominantly employed that can be rapidly administered. The two tests are often used in conjunction, while the more sensitive D-15d is widely employed for early detection of mild neurotoxin-induced dyschromatopsias. The observer is presented with a set of color caps and requested to arrange them in ("rainbow") sequence. The D-15 test was designed to diagnose moderate to severe color defects; the Lanthony D-15d test, similar in design and identical to the D-15 test in administration, consists of color samples that are lighter and paler [6] and was designed specifically to capture mild or subclinical color defects in observers who pass the standard D-15 test. Outcomes of both tests are easily interpreted allowing color vision ability to be quantified graphically [5]. Further, the number of erroneous cap transpositions provides a measure of overall color discrimination; the pattern of the transpositions indicates whether the defect is

closer to the blue-yellow or red-green axes or with no discernible pattern. The outcomes of the D-15 and D-15d are reported via a Color Confusion Index (CCI), where 1.0 corresponds to perfect color arrangement; CCI values greater than 1.0 indicate progressive impairment of color discrimination [5, 6] (Fig. 1).

Occupational Exposure to Neurotoxic Substances

A number of occupations involve exposure to volatile neurotoxic substances (e.g., printers, aircraft maintenance workers, dry cleaners in automotive and metalworking industries, viscose rayon workers, microelectronics assembly workers, gold miners, dentists, etc.). Such substances include organic solvents (toluene, styrene, benzene, perchlorethylene, *n*-hexane, carbon disulfide), solvent mixtures, and metals like mercury (in its elemental or methyl forms). Even when neurotoxic substances are applied within the occupational limits, long-term exposure has been shown to result in mild impairment of color discrimination [7–9].

Using the D-15d test, the degree and pattern of color vision loss were intensively investigated with regard to exposure to organic solvents, in particular toluene and styrene [2, 7–10], and to mercury [11]. The main finding across these studies is significant increase of the CCI in the occupationally exposed observers (compared to age-matched controls). For example, in a meta-analysis of 15 sample studies of the effects of toluene, styrene, and solvent mixtures [9], the grand mean CCI for the exposed workers was 1.22 ± 0.08 , significantly greater than 1.13 ± 0.06 for the controls ($p = 0.003$). Similarly, in [11], for workers of fluorescent lamp production exposed to mercury vapor, $CCI = 1.14 \pm 0.14$ was significantly greater than $CCI = 1.04 \pm 0.06$ for controls ($p = 0.002$). The impairment of color discrimination was shown to be subject to cumulative exposure, i.e., product of duration and current level of exposure [2, 7–10], and may become irreversible even when the hazardous agent is withdrawn [11].

Color Perception and Environmentally Based Impairments, Fig. 1. Scoring sheet for the D-15 (a) and the D-15d (b); for illustrative purposes, the numbers are accompanied by colors simulating those of the original test caps. At perfect color arrangement of a normal trichromat, lines connect the “reference cap” through 1–15; CCI = 1.0. (c, d) Lines are drawn between consecutive

caps as placed by a protanope, observer with a congenital red-green deficiency; (c) CCI = 2.48; (d) CCI = 3.11. (e, f) Mild acquired tritan (blue-yellow) type of color discrimination impairment; (e) CCI = 2.06; (f) CCI = 2.19. Note that the low-saturated stimuli of the D-15d result in a more prominent color confusion (d, f)

Neurotoxin-induced dyschromatopsias are predominantly of Type III, i.e., of tritan-like pattern. Less common are Type I and II, red-green dyschromatopsias. In comparison, the non-specific type of dyschromatopsia is also highly prevalent, which implies difficulty in discriminating colors along both the red-green and blue-yellow axes of color space (Color Vision, Opponent Theory).

Self-Administered Consumption of Substances Containing Neurotoxic Chemicals

Chronic excessive consumption of alcohol (ethanol) affects color discrimination capacity [6, 7]. When assessed by the D-15d test, the prevalence of dyschromatopsia was shown to increase with alcohol intake. Further, heavy drinkers (with an intake larger than 750 g/week) manifested primarily loss of blue-yellow discrimination, whether or not they were undergoing treatment in a detoxification center. However, 25% of persons undergoing detoxification revealed dyschromatopsia of the nonspecific type, including red-green loss [12].

Tobacco smoke contains a range of compounds including nicotine, cyanide, and carbon monoxide and, when consumed excessively, can affect color vision [1, 13]. When tested by means of the color arrangement tests, chronic smokers (>20 cigarettes/day; for at least a year) revealed a subtle but statistically significant reduction in sensitivity to red-green differences compared to non-smokers [14] or showed a diffuse character of color vision disturbance, without a particular dyschromatopsia axis [15].

Side Effects from Pharmacological Treatments

A number of medications (e.g., cardiovascular, antiepileptic, antituberculosis, antirheumatism drugs, oral contraceptives, etc.) are known to

produce measurable color vision disturbances, some of which affect color vision even at therapeutic levels, most commonly as Type III, tritan-like blue-yellow dyschromatopsia [1, 3, 6, 7, 16]. For instance, patients taking antiepileptic drugs develop mild blue-yellow deficiency which may show signs of progression with lasting intake of the drugs. Intake of Viagra was shown to cause transient adverse visual events described as a blue color tinge to vision, accompanied by mild blue-yellow deficiency in about 11–14% of those taking the medication, the disturbance being reversible after the medication has been discontinued. Treatment by the tuberculostatic ethambutol shows mild blue-yellow deficiency as the earliest sign of the drug's neurotoxicity, but this can also develop as Type II, deutan-like red-green, or a nonspecific dyschromatopsia; these defects are transient and reversible after stopping the therapy.

Consumption of Food Contaminated by Neurotoxic Elements

Certain industrial activities, like gold mining or mercury mining, are associated with pollution of mercury which bioaccumulates mainly through the aquatic food chain (seafood and fish). Even at low levels of dietary exposure, mercury was shown to chronically reduce color discrimination, with the error pattern indicating that both blue-yellow and red-green systems are affected, when the FM100 test, D-15d test, and the Cambridge Colour Test were used (► [Color Vision Testing](#)) [17, 18].

Color Phenomenology

Don Dedrick

Department of Philosophy and Department of Psychology, University of Guelph, Guelph, ON, Canada

Synonyms

Color experience; Color qualia

Definition

The word “phenomenology” finds its original application in philosophy, and it has two distinct meanings in that discipline. In the first, most substantive meaning it refers to a philosophical tradition originating in the work of G. W. F. Hegel and developed in the work of Edmund Husserl, Martin Heidegger, Jean-Paul Sartre, and others, with the psychologist Franz Brentano as a major influence [11]. In this primordial sense, it refers to a non-psychological description of the fundamental constituents of experience. It may sound peculiar to call an account of experience “nonpsychological” since experience might be thought of as necessarily psychological. The rationale for the usage is this: one may possibly describe the fundamental constituents of human experience – concepts, ideas, propositions, temporality, mental images, etc. – in a way that captures their generic character and hence their “universality” rather than their specific contents. Such a view articulates, so classical phenomenologists say, the logical or

conceptual structure of experience. The second application of the term refers more directly to the *mere* appearance of things. There is no universality attached to such description. It is, rather, a reference to the way things *seem* to perceivers: red looks this way (and perhaps just to an individual), pain feels this way (ditto), dogs bark in a way that sounds as it sounds (again, perhaps just to the individual). This sense of the word “phenomenology” (the words “qualia” [10] or “experience” are sometimes used) describes the way that many Anglo-American philosophers have deployed the term throughout much of the twentieth century, into the twenty-first. This second sense has clear links to the way experimental psychologists talk about colour experience, especially when they refer to the psychological, sensory aspects of color: hue, saturation, lightness/brightness, and other aspects of color appearance [8]. It is this second sense that is of interest here.

Color Phenomenology and Ontology

If the phenomenology of X concerns the way that some X *seems*, is a contrast to the way things *are* implied? The answer is yes. Consider the following example (discussion will now concern examples and issues specific to color phenomenology). As one moves a color stimulus from one illumination source to another, one will notice that it appears to change color, though likely within the bounds of color constancy. This may lead to a question as to its “real color,” and that question may lead in a number of directions. Perhaps its real (object) color is identical with a physical property that does not change across illuminations: surface spectral reflectance, for example. Perhaps the idea of real color should be abandoned and replaced with a conception of color relativized to viewing conditions and observers. Perhaps one could speak of a “normal observer” (as the CIE does) so as to wring some objectivity out of the phenomenology.

These positions take up different views as to the relation between the way things seem – color phenomenology – and the way things are, ontologically, for color. There is a spirited, scientifically informed philosophical literature that covers

many permutations of three general views which are typically called, with some variation, *objectivism* (color is in the world), *subjectivism* (color is in the mind-brain), and *relationalism* (color is constituted in a relation between the mind-brain and the world). There is currently no consensus among philosophers as to which type of view is correct. All three exhibit strengths as well as weaknesses. To consider one example: an objectivist view allows us to distinguish between the colour of an object and its colour as perceived by a subject. That is an obvious strength. On the other hand, objectivist views find it difficult to specify an appropriate candidate for objective color. It is not just that there are many actual physical causes of color experience, but that the actual causes are often identified by reference to experience itself. The colour red, for example, seems to be, objectively, whatever it is that causes a red color experience. That is a weakness. (See [1, 5] for discussion of this and related issues.)

Epistemological Issues

Questions about real colors are questions about ontology. Does the catalogue of the real include colors? What is a real color, if there is such? As important as these questions are, much of the interest when it comes to color phenomenology is not ontological but epistemological: what can be known, and what are the limitations to what can be known, about color experience? The most famous query along this line comes from John Locke. In the *Enquiry Concerning Human Understanding* [6], Locke proposes that a “spectral inversion” would not be detectable. Subject A and subject B, indistinguishable in terms of their behavior on discrimination tasks, nonetheless have different experiences. Subject A’s experiential color space is “inverted” relative to B’s. For Locke, this meant that A and B use color words the same way, describe their color experiences the same way, discriminate color stimuli in the same way, and yet have distinct color experiences, e.g., Subject A’s green is B’s red, and vice versa, and the same goes for blue and yellow, etc. Thus, the inversion is behaviorally undetectable. Many consequences have been

thought to flow from Locke's proposal (that, for instance, behaviorism is false as a theory of psychology), but vision science provides good reason to believe that even if such inversion were possible, it would be detectable. The inverted spectrum proposal depends on a color space that is symmetrical so that one can map discriminable differences one-to-one from, say, the "greens" to the "reds." This condition is not satisfied for a standard human trichromatic color space, as specified, for instance, in the asymmetrical CIE $L^*a^*b^*$ space. The upshot, in terms of behavior, is that A and B would behave differently – confusing or discriminating different color stimuli. The inversion, with the cleverness of psychophysics, would be detected [2].

Despite the fact that Locke's proposal appears to fail, its implications are not easily dispatched. Even if spectral inversion can be detected, the question remains as to what color experience is like. Consider the following line of reasoning. What is to be learned from the psychophysics of color? This is a broad question, but broadly the answer would be that one learns correlations between different types of stimuli and different types of behavior. From these correlations, serving as constraints, ideas as to what the properties of the neural substrate of color experience need to be like may be formulated, models constructed, convergence with other areas of physiology and psychology sought. Psychophysics (visual being the concern here) is a mature subdiscipline of psychology, but does it deal with the way things – colored things – look? This sounds an odd question for a science that is based on subjects looking at visual stimuli and responding to them. How could it not deal with this? Yet vision scientists are uneasy about the claim that discrimination data say something reliable about the content of experience. If one asks a subject what red looks like, the subject will revert to demonstrative claims – it looks like *that* – or to relational claims locating a red color sample in relation to that of other colors: more like orange and yellow, less like blue and green. While these descriptors are often robust for subjects, they do not, or so it is often claimed, get at the subjective nature of color experience. In a very influential article, "What is it like to be a bat?" [7] Thomas Nagel argued that we

cannot access the subjective experience of others from a scientific third-person perspective. Bat's, Nagel proposed, have experience – there is something that it is like to be a bat (as opposed to, say, a stone). While one can use the techniques of animal ethology, biology, and bat psychophysics to determine bat discrimination space, the content of the bat's experience is beyond the grasp of those third-person methods – beyond an objective third person science and its "view from nowhere." Nagel's argument really has little to do with bats. They are a useful exemplar since it is easy to imagine (a) that bats have experience and (b) that their experience is distant from human experience. In this sense, the bat is a foil to arguments from analogy: one can believe that bats have experience, but there is no analogy to human experience to guide us because echolocation is a different sensory modality than either sight or hearing. The central thrust of Nagel's argument concerns subjectivity. There is a subjective view of the world that science, as humans presently know it, cannot access. Human subjectivity is, in the end, just as mysterious from the third person point of view as is the bat's. This is why many psychophysicists are likely to be in agreement with philosophers skeptical about our knowledge of color phenomenology – why it is that psychophysicists are uneasy about any inference from discrimination to experience – inference from the judgments subjects make on discrimination tasks to the nature of their experience.

Not all philosophers, and certainly not all scientists, vision or otherwise, accept the view that subjective experience – including color experience – is mysterious from a third-person perspective. One might argue that a good model of an individual's discrimination space for color is as good as the human behavioral sciences get. If, for example, a subject fails to discriminate images in some set of pseudoisochromatic color plates, then one can make predictions about their future discriminatory behavior and also explain that behavior. Such tests do more than identify types of "color blindness"; they identify the axes on which colors are confused and may correlate such confusion with genetic differences in opsin expression at the retinal level. What more could

one want? It seems that there are two things: (1) an account of *what* the subjective experience of color is like, as opposed to a third-person take on that experience – this is Nagel’s concern and (2) an account of *how* subjective experience is generated (how it fits in with the ontological “catalogue of the real”) – this is a concern most closely identified with the Australian philosopher David Chalmers [3].

Chalmers writes mainly about consciousness, but his views on that subject have clear implications for color phenomenology. Unlike Nagel, who makes a case for the subjectivity of experience and is concerned with how that experience might be understood scientifically, Chalmers argues that the real problem with experience is that science has no idea as to how it is generated by a physical system (and, more radically, *why* there should be such experience in the first place). Chalmers is not denying there is subjective experience. We have experiences of color, unquestionably. He is claiming that the causal account we give of such experience is incomplete. Suppose one could understand color perception “all the way up”: from stimulus presentation, to photon-absorption at the retinal level, to retinal and LGN opponent processing, to cortical processing in the visual areas of the brain, to integrative processing in the executive areas, to the output of discrimination-based behavior which is a function of this whole process. While vision science understands some elements of this causal story quite well, and others not as well, even *perfect* understanding of it might leave science in the dark as to how color experience is generated. At what point do the biological properties of brains cause or constitute experiences of color, and how? Chalmers argues that the science of consciousness, such as it is, has no idea how to even address, let alone answer this so-called “hard question” – “hard” not in virtue of the difficulty of the science (as with the molecular biology of vision, say) but “hard” in the sense that science offers *no advice* on how to bridge the gap between its cognitive-neurobiological accounts of the brain, and the experience that brain is thought to generate. In response to the idea that there is such a hard problem, critics of Chalmers have typically

adopted one of two approaches (see the commentaries reprinted in Ref. [9]): (1) argue that Chalmers assumes the limitations of current brain science are permanent (this involves the positive claim that problems that look “hard” at a given point in time may become easier with new developments in theory and practice) or (2) argue that early progress has, even now, been made on a complete theory of conscious experience.

With respect to the first strategy, one can quite agree that, in the future, science is likely to succeed in areas currently unimagined. Yet (1) does not address the request for a way forward on the problem of brains generating experience but merely points out that science will almost certainly find new ways of addressing (or disposing of) the problem. This may be true, but the argument is not substantive, given the claim that the nature of experience and its origins is a different sort of problem altogether. If one claims that the march of science will be sufficient to explain the generation of conscious experience at some point in time, then one is simply denying Chalmers’ claim and that, arguably, assumes what it should demonstrate. As for (2), the view that progress has been made on the explanation of consciousness, Chalmers has pointed out that contemporary empirical theories of conscious experience (a) shift the problem of experience and how it is caused or constituted to accounts wholly within cognitive neuroscience and biology – an account of attention, say, or an account of neural opponent processing for the case of color. As a consequence (b), such accounts will provide, at best, accounts of the “neural correlates” of conscious experience rather than an account of how conscious experience is generated by neurobiological function.

Color Phenomenology and the Structure of Color Experience

Claims that science does not understand how phenomenological experience arises or is constituted from neurobiological function, or that a complete understanding of human phenomenology surpasses what can be known from a third-person scientific perspective sound dire: as if experience

is not understood at all. And yet it is remarkable how much about the phenomenology of color can be examined “from the outside” – and from a position of ignorance as to the ultimate causes of that phenomenology. As noted earlier, psychophysics would be able to identify the spectral inversion that has troubled philosophers. Such detection really is no different, in principle, than the detection of different forms of dichromacy: protanopia, deuteranopia, and tritanopia – all involving failure to discriminate among stimuli that a normal trichromat would discriminate. Each of these deficiencies (relative to trichromacy) is a consequence of the lack of one or another of the three typical photoreceptors. They are physiologically based effects that can be identified through behavioral tests, and, moreover, vision science can explain the relevant deficiencies and their fine-grained differences at physiological and genetic levels. A color space for the dichromat, as for the trichromat, can be pieced together from various behavioral judgements, a difficult and arduous task. Color science has, in other words, a reasonably good grasp of the *structure* of human (primate) color experience [4], as well as its physical and neurophysiological correlates, even if the precise, personal, subjective nature of that experience as well as its generation by physical systems such as brains remain epistemically problematic.

Visual pollution

Definition

Color pollution consists of an inappropriate color arrangement which causes or increases disorder in the perception of the visual field within an urban or natural environment. It is an important aspect of visual pollution.

Overview

Color Pollution as a Component of Visual Pollution

In the context of environmental design, visual pollution refers to all nonarchitectural elements which spoil, in an invasive and simultaneous way, the perception of outdoor spaces. These features range from plastic bags trapped between tree branches to publicity panels, street signs, posts, and wires [1]. Besides the unaesthetic consequences the unnecessary exposure of these elements may bring, visual pollution leads to the overstimulation of the senses, increasing the load of information to be processed by viewers, drivers, and pedestrians.

Light and color are important aspects of visual pollution. The first one generates luminous pollution or light pollution due to artificial lighting and the second one generates color pollution by the introduction of cultured elements. Color pollution may originate in visual pollution, when it is the consequence of an inconveniently positioned feature which reinforces its presence by color. Otherwise, it may be a color that is incoherent within the composition and causes disorder. The disharmonious result may be produced by one or more color dimensions (hue, saturation, and lightness) [2]. Achromatic colors are necessary for creating transition spaces between color information, though black, white, and gray may also produce an effect of color pollution by lack of tone and contrast in luminosity.

Negative Impact of Color in the Environment

Color affects the perception of objects and compositions within a setting. It serves to codify elements and establish visual hierarchies. If used randomly, disregarding its power, color may easily draw attention to misleading data, distracting the viewer from relevant information for the interpretation of a scene [3]. When inappropriate colors are used in minor elements such as urban furniture, advertising panels, or building elements, color, far from being a useful signal, ends up invading the environment with an ambiguous and arbitrary presence.

Color as Intended by Nature and Adaptation to Color Coding

Colors in nature convey physical and chemical characteristics. They also give information on material processes and ethereal substances. In the animal kingdom, color has a biological role, as an aid to survival [4]. In natural conditions, human beings would respond to colors by instinct, using them as intended by nature: for alerting and announcing danger, for recognizing food and bodily functions, and for perceiving space and distance.

The man-made environment is full of visual information and signals, many of which are based on color. Universal coding by color distinguishes hot from cold, gas from water, forbidden from allowed, and so forth. Color is present in domestic and work activities. When shopping, colors in packaging and logos inform about names and brands, colored tags serve to mark sales from regular prices, while bright and fluorescent colors indicate special deals.

When color is used inadequately, the information it conveys becomes irrelevant and negative for the user, causing confusion and contributing to visual pollution. Man possesses a biological memory that keeps him aware of color signals, but using this faculty amid color excess and randomness may prove a waste of energy, causing fatigue and stress.

Color Pollution in Cities

Color pollution exists in the urban environment, predominantly in cities and villages. Commercial and mixed-use areas are good examples of competition for capturing attention. In isolation, color communication is effective. The use of written signs and subtle colors may work too, but among competing signs, these no longer accomplish their intended function, promoting other formulas to be put into practice: brighter colors, contrasting backgrounds, larger letter types, images, lighting, and many others [5]. The arrangement of the signs may easily become visual pollution, while the excessive and inappropriate use of color contributes to a chaotic environment.

The effects of color pollution are negative. Bright and saturated colors tend to spread in the

scene, as others are induced to use the same strategy. In cities, color tends to go out of control in commercial panels. Traffic and safety signs [2] diminish their effectiveness when there are objects with similar colors around. Associations between certain colors and objects, which have not been planned carefully, tend to become ingrained in a cityscape, that is, urban furniture, bridges, and signals. From that base, the rest is decided or added on.

Architectural elements may cause color and visual pollution within a façade by producing imbalance in the composition. When building exteriors invade the visual field with bright and saturated colors, far from enhancing architecture, these threaten the aesthetic aspect of the environment.

Color Pollution in Natural Settings

Natural settings are highly susceptible to visual and color pollution. This occurs when man-made elements are introduced in a landscape, with no regard to material quality and color, resulting alien and obtrusive. It is common to find posts, cables, advertising, and constructions invading the visual field, interrupting the continuity of mountain ranges, seascapes, agricultural fields, and woods. The position, size, and frequency of these elements are relevant. Additionally, their impact may be emphasized or diminished by materials and colors. For instance, a black plastic water tank may be very disruptive when placed against a mountain backdrop. Its visual impact would be attenuated if it were beige, echoing the color of the background.

Consequences of Color Pollution

As occurs with noise and visual contamination, color pollution may be aggressive, causing fatigue and stress. Slow reactions and traffic accidents may be caused by excess of information and distracting colored elements. As color pollution affects the aesthetic aspect of a place, users may find it hard to enjoy and develop a sense of belonging in visually disrupted settings.

Though the perception of color in animal species differs from that of humans, pollution by

color may diminish the chances of wildlife establishment near human conglomerates. In prey birds and day birds, which have an acute and sophisticated sense of vision, color plays specific functions in mating and feeding [2, 6]. The presence of artificially colored elements in their habitat may affect their behavior by alerting and confusing them.

Causes of Color Pollution

If color does not correspond to function nor to survival or aesthetics, who is to blame for its randomness? Lack of regulation and guidelines for the use of color allow the invasion of contaminating colored elements in the environment. This is a major deficiency of cities and natural settings. The causes of color pollution also rely on the consumer society, the commercial offer of paint and cladding materials, and visual marketing strategies.

Man, with his ability to synthesize and create from the materials which are granted to him, uses color to express, symbolize, and communicate ideas. The evolution of coloring mediums, tools, and technologies has resulted in an overwhelming variety. By contrast, the rules for the application of these advancements are scarce.

Municipalities rent strategic spaces to corporations for publicity. Owners will rent the roofs of their houses to advertising companies, if they are not prevented to do so. To the detriment of the setting, a gigantic beer can or a credit card could become a focal point. The colors used in these advertisements are centered in the product, not in the environment, and very often result in color pollution.

It appears as common practice in many parts of the world that, at the time of political elections, propaganda invades city and countryside. Usually the combination of two primary colors of medium to high saturation and black is used over a white background, producing a contrasting figure-ground relationship which is legible from a distance [5]. Recurring examples of visual and color pollution of this sort remain on walls and along roadsides long after the campaigns are over.

It is for sure that the cultivated and sensitive individual values unspoiled scenery more than

authorities and inhabitants of rural towns, where the beauty of natural sights seems to be taken for granted.

Solutions for Color Pollution

Authorities have in their hands the possibility to control the environmental impact caused by political propaganda and commercial advertising through regulations and sanctions.

Decisions for preserving and improving environmental colors are common ground of authority and designer. It is necessary to assess the environment and develop regulations according to its unique qualities, visual advantages, and important buildings. These should be taken as standpoints for design and planning. The design of features to go in a landscape or cityscape should be thoughtful and consider the particular characteristics of the setting, including color. Color is a powerful tool but is just one of many in a composition. Parameters regarding order, geometry, repetition, size, shape, and material should be part of the regulation criteria.

Reducing the variety and amount of elements in the visual field is crucial. Color may be protecting or decorating some element, which is obtrusive per se. The addition of features, such as signals and urban equipment, requires planning and restrictions in the color aspect too. In particular cases, the introduction of greenery may help to cover up the obtrusive elements, to create structure and order in the visual field or to balance a composition.

The adjustment of color dimensions (hue, saturation, and lightness) may be effective for resolving certain visual conflicts. Through the use of adequate colors, annoying features could be neutralized or kept inconspicuous. In this way, color would serve the purpose of contributing to visual order.

How much people like different colors

Main Text

One of the most fascinating aspects of color cognition is that people have strong preferences, liking certain colors and color combinations much more than others. What is known about human

color preferences, not only in terms of *which* colors and color combinations people like but also *why* they like them, will be discussed below.

Preference for Single Colors

Average color preferences for a given sample of colors are typically measured behaviorally by asking a group of people to perform one of the following tasks [9]. First, observers can be asked to indicate which of two simultaneously presented colors they prefer for each possible pair of colors in the sample. The probability, averaged over observers, of choosing each color versus all other sample colors is then taken as a measure of its average relative preference within that sample. Second, observers can be shown all of the colors in the sample simultaneously and be asked to rank order them from most preferred to least preferred. The average rank of each color across observers provides a measure of average relative preference within the sample. Third, observers can be shown a single color on each trial and be asked to rate their preference for it on a discrete (e.g., 1–7) or continuous (e.g., marking along a line segment) rating scale. Average ratings across observers can then be taken as a measure of average relative preference for colors within the sample. Fourth, observers can be shown colors in a continuous space, or a sample of such colors, and be asked to select which color(s) they most like and most dislike. Responses are aggregated across observers to form frequency distributions of most liked and most disliked colors, which may be integrated (e.g., frequency liked minus frequency disliked) to arrive at overall preference measures or analyzed separately [5]. Color preference patterns using these different measures tend to be quite similar when the same observers (or large samples of different observers from the same population) judge the same colors.

Early researchers often claimed that color preferences were too idiosyncratic to be worth empirical study, but modern measurements of well-calibrated, computer-generated displays of standardized colors using improved data analysis techniques have now established that there are reliable and repeatable patterns in group data [17]. These average color preferences are most

easily understood in terms of the three primary dimensions of human color experience (see chapter ► “Color Spaces”): hue (its “basic color”), saturation (how vivid or pure the color is), and lightness or brightness (how light versus dark the color is). Figure 1 plots average adult preference ratings in the USA for 32 chromatic colors, consisting of eight hues – red, orange, yellow, chartreuse (yellow-green), green, cyan (blue-green) blue, and purple – in shades that are either highly saturated, light, muted (desaturated, mid-level lightness), or dark [8].

As Fig. 1 shows, average color preferences show a clear maximum around saturated blue and a clear minimum around dark yellow (greenish brown or olive). The majority of this variation is due to differences along the blue-to-yellow dimension of hue, with bluer colors being generally preferred to yellower colors. There is much less variation in the red-green dimension. In addition, people generally prefer more saturated colors over less saturated ones, with little difference between the light (pastel) and muted tones, at least in the USA. (See chapter ► “Color Preference”.) The most interesting finding theoretically is the striking difference between the shape of the hue preference curve for dark colors versus those for the saturation-matched light and muted colors. In particular, there are decreases in

Color Preference, Fig. 1 Color preference ratings in the USA as measured by Palmer and Schloss (2010). Preferences for the saturated, light, muted, and dark colors are plotted as a function of hue: red (R), orange (O), yellow (Y), chartreuse (H), green (G), cyan (C), blue (B), and purple (P)

preference for dark-orange (brown) and dark-yellow (greenish-brown or olive) relative to the light and muted oranges and yellows and modest increases in preference for dark-red and dark-green relative to the light and muted reds and greens [8]. The overall pattern of adult preferences for single colors is thus complex but clear and replicable. For a more extensive review of modern studies of single color preferences, the reader is referred to Whitfield and Wiltshire [17].

Describing Patterns of Color Preferences

Various types of models have been used to describe patterns of color preferences using different sets of predictors, typically computed using multiple linear regression. These models provide a parsimonious way to describe patterns of color preferences of groups or individuals, simply by specifying the weights placed on each of the predictors. One series of models used predictors that correspond to different stages of visual processing. The first was the *cone contrast model*, which used a weighted average of cone contrasts relative to the background. Cone contrasts are believed to be computed very early in visual processing: $L-M$ and $S-(L + M)$, where S , M , and L represent the outputs of cones maximally sensitive to short, medium, and long wavelengths of light, and was later extended to include luminance ($S + M + L$) and saturation [4]. The *color appearance model* tested higher-level color appearance dimensions, using a weighted average of observer-rated redness-greenness, blueness-yellowness, saturation, and lightness of each color, roughly analogous to their coordinates in the natural color space (see chapter ► “[Psychological Color Space and Color Terms](#)”) [8]. A third type of model tested perceptual dimensions cylindrical coordinates in CIELAB color space, using a linear combination of the 1st harmonic over hue angle (reflecting preference for a dominant hue, such as blue), a 2nd harmonic over hue angle (reflecting preference for both ends of a dominant opponent axis, such as red and green), lightness, and chroma [10]. Comparisons across model types demonstrate that higher-level predictors (e.g., color appearance and cylindrical coordinates) better describe color preferences than

lower-level predictors (e.g., cone contrast); see [10] for a review and more details on modeling color preferences using color space metrics.

Another type of model aimed at describing color preferences used *color emotions*, which are associations between emotion-related terms and colors [7]. A large set of color emotions can be reduced using factor analysis, producing factors such as *active-passive*, *light-heavy*, and *cool-warm*. Those factors are used to describe color preferences using linear regression techniques [11]. Evidence suggests that models using color emotions describe color preferences nearly as well as color appearance dimensions do [2].

Explaining Color Preferences

This far, this entry has focused on describing *which* colors people like and dislike. But *why* do they like the ones they like? Indeed, why do people have color preferences at all? One theory that is that color preferences are hardwired into the visual system to serve an adaptive function on an evolutionary time scale [3]. However, evidence demonstrating individual differences and temporal changes in color preferences suggests that a large aspect of color preferences is learned through experiences (see [12] for a review). These differences, as well as the general pattern of color preferences in Fig. 1, can be explained by the ecological valence theory (EVT). Originally, the EVT posited that people like colors to the degree that they like the environmental objects that are characteristically those colors [8] but has been extended to include all concepts associated with colors (e.g., objects, entities, and events) [12]. For example, people tend to like blues and cyans because they like blue things on average (e.g., clear sky and clean water) and they tend to dislike browns and olive colors because they dislike brown and olive things on average (e.g., biological waste and rotting food). The theoretical rationale of the EVT is that it will be adaptive for organisms to approach objects and situations associated with the colors they like and to avoid objects and situations associated with the colors they dislike to the extent that their color preferences are correlated with objects and situations that they like versus those that they do not like.

This does not mean that color preferences are irrelevant to object preferences: clearly they matter for functionally identical artifacts that are available in many colors (e.g., clothes, furniture, cars, and appliances). However, the EVT suggests that those color preferences arose initially from associations with characteristically colored objects and were then positively or negatively reinforced by positive or negative experiences associated with those colors.

Support for the EVT was first provided through empirical measurements of the weighted affective valence estimates (WAVEs) for the 32 chromatic colors in Fig. 1. The WAVE for each color measures the extent to which people like the objects that are associated with that color. It was computed from observers' average valence (liking/disliking) ratings for *all* things named as associates for each color studied, with each valence rating being weighted by the similarity of the given color to the color of that associate. Although blue is strongly associated with objects that are almost all liked (e.g., clear sky, clean water, swimming pools, and sapphires), most colors have associates with both positive and negative valences. Nevertheless, the WAVE, computed as specified above, explained 80% of the variance in the data shown in Fig. 1 with no estimated parameters. Further support came from studies showing that individual differences in color preferences could be accounted for by individual differences in preferences for objects associated with colors. Moreover, studies using a controlled priming task and natural variations over seasons demonstrated that color preferences systematically changed over time, depending which concepts were activated in people's minds. For example, priming people to think about ripe strawberries and roses (positive in valence) led to an increased preference for red. Both individual and temporal differences can be understood within a single theoretical framework [12].

Development of Color Preferences

Infant color preferences are studied by examining the looking behavior of babies when they are shown pairs of colors side by side. It is generally

assumed that the color at which the baby looks longer and/or first is preferred to the alternative. Color preferences are therefore measured by determining the average looking times and/or the probabilities of first-looks [15]. Infants younger than about 3–4 months tend not to be studied because the short-wavelength sensitive cones do not mature until that age, making them functionally color deficient relative to adults (see chapter ▶ “Effects of Color Terms on Color Perception and Cognition”).

When infant looking preferences are measured for highly saturated colors, the hue preference function tends to have roughly the same shape as the corresponding adult hue preference function, with a peak around blue and a trough around yellow-to-yellow-green [5]. Great care has to be taken to ensure that hue-based color preferences actually reflect differences in hue by controlling for luminance, brightness, discriminability, colorimetric purity, and saturation. More recent studies that directly compared infant preferences with those of adults for less saturated, but better matched, colors have found important differences, however. In particular, infant preferences for these color samples vary primarily on the red-to-green dimension, with redder colors being more preferred, and do not vary much on the blue-to-yellow dimension [2]. Because this pattern for infants is opposite that for adults, color preferences either must be subject to learning as a result of experiences with differently colored objects or there must be a substantial maturational process that influences color preferences.

As children develop, gender differences begin to emerge. For example, 1-year-old children show no difference in preference for pinks vs. blues, but around 2, girls tend to prefer pinks more than boys do [6]. This has been explained by the corresponding gender differentiation in toys, where toys marketed for girls tend to come in pinks and toys marketed for boys tend to come in blues. Thus, this gender differentiation in color preferences can be explained by the EVT, within which children come to like colors associated with objects they like. The role of gender in adult color preferences is still an open question [4].

Color Preferences in Different Contexts

A question of applied interest is how adult color preferences for patches of “context free” colors, as described above, generalize to preferences for colored objects. Presumably, they would not generalize for natural objects that have prototypical colors (e.g., not preferring bananas in blue, given their natural colors are yellows/greens), but generalization is evident for artifacts that could, in principle, be produced in virtually any color, such as shirts, walls, sofas, and cars [14]. Some have shown that hue preferences are fairly consistent across different types of objects, with differences occurring primarily in lightness and saturation [14]. For example, people generally preferred lighter walls and darker couches and disliked saturated colors for most contexts even though saturated colors were most preferred for contextless colored patches. These variations seem to depend on practical considerations, such as walls being preferred in lighter tones that make rooms appear more spacious and couches being preferred in darker shades that hide dirt. However, others have suggested that hue preferences are more variable across contexts [5], and more research is needed to fully understand how and why color preferences vary with context.

Preference for Color Combinations

Chevreul formulated a highly influential art-based theory of color harmony (or color preference, because he used the terms interchangeably), which claimed that there are two distinct types: *harmony of analogous colors* and *harmony of contrast* [1]. In brief, harmony of analogous colors includes *harmony of scale* (colors of the same hue that are similar in lightness) and *harmony of hues* (colors that are similar in hue and the same in lightness). Harmony of contrast includes *harmony of contrast of scale* (colors of the same hue that differ in lightness), *harmony of contrast of hues* (colors of similar hue that differ in lightness), and *harmony of contrast of colors* (colors that differ in both hue and lightness). Other theories include Itten’s claim that combinations of colors are harmonious provided that the colors produce neutral gray when mixed as paints, Munsell’s and Ostwald’s theories that colors are

harmonious when they have certain relations in color space (e.g., they are constant in hue and saturation but vary in lightness), as well as other theories proposed by Goethe and Moon and Spencer [16]. None of these theories was formulated on the basis of aesthetic measurements, although some have since been tested empirically.

Empirical Research on Color Pair Preference and Harmony in Combinations

The confusion surrounding preferences for color pairs can be clarified by distinguishing among three different concepts: *pair preference*, *pair harmony*, and *figural preference*, for a color against a colored background [11]. *Pair preference* is how much an observer *likes* the combination of the two colors as a whole. *Pair harmony* refers to how well the two colors *go together*, regardless of whether the observer likes the combination or not. This distinction between preference and harmony can be understood by analogy to music, wherein nearly everyone would agree that Mozart’s music is more harmonious than Stravinsky’s, but some prefer Mozart, and others prefer Stravinsky. *Figural preference* denotes how much the observer likes the single color of the figure when viewed against a different color in the background. Although figural preference involves a judgment about the single color of the figure, it is relevant to preferences for color combinations because the same color can look strikingly different on different background colors (see chapter ► “Simultaneous Color Contrast”).

Figure 2A shows average preference ratings for color pairs as a function of the hue of the figure (x-axis) and that of the ground (the different curves). The primary pattern in the data is that, for every background hue, people prefer combinations in which the figure has the same or a very similar hue. On average, people tend to like color combinations that are the same or similar in hue but differ in lightness, which Chevreul called harmonies of analogous colors. There is no evidence for Chevreul’s harmonies of contrast, however, because there are not reliable increases in the functions at opposite hues (e.g., red and green). A secondary fact is that people tend to like color combinations to a degree that reflects their

Color Preference, Fig. 2 Rated preference (a) and harmony (b) for pairs of colors as a function of the figural hue (x-axis) and ground hue (different curves)

preferences for figure and ground colors, with combinations on blue backgrounds being generally most preferred and those on orange backgrounds being least preferred. This tendency is relatively minor, however, accounting for only 22% of the variance in preference ratings.

Harmony ratings of the same color pairs are plotted in Fig. 2B. They are similar to preference ratings, but the peaks at same hue combinations are even more pronounced. This similarity explains why preference and harmony have so often been equated, but there are differences between the two measures. Pair preference depends more on preference for the component colors within the pair, and harmony depends more on color similarity.

Ratings of figural preference for colors against colored backgrounds are measurably different from ratings of both pair preference and pair harmony, showing clear effects due to the hue contrast and lightness contrast of the figure against the background: warm figures (e.g., red, orange, and yellow) were preferred against cool backgrounds (e.g., green, cyan, and blue) and vice versa [14]. It appears that what Chevreul termed harmonies of contrast actually apply to judgments about preferences for figural colors when viewed against different colored backgrounds. Given the general preference for saturated colors described previously, it is not surprising that observers prefer

figural colors against highly contrastive background hues, because these would produce the strongest simultaneous color contrast effects, thus increasing the perceived saturation of the figural region.

Theories of Preferences for Color Combinations

The foregoing describes which color combinations people prefer and which ones they find harmonious, but why do these variations in preference and harmony arise? To the extent that pair preferences are influenced by preferences for the component colors, ecological associations of colors with objects are one important factor. Pair preferences are also influenced by people's positive/negative associations with objects and/or institutions that are associated with those colors in combination (e.g., red and green with Christmas). In a related vein, Schloss, Poggesi, and Palmer [13] investigated preferences for school colors among Berkeley and Stanford students: blue and gold for Berkeley and red and white for Stanford. They found that Berkeley students liked Berkeley color combinations better than Stanford students did, and Stanford students like Stanford colors better than Berkeley students did, with these effects increasing with increasing amounts of self-rated school spirit. Such results clearly imply that ecological effects are present in preference

for color combinations as well as for individual colors.

Perhaps the most important finding about preferences for color pairs is that people generally like harmonious combinations of the same (or similar) hue that differ in lightness. Although it is not immediately obvious why this might be the case from an ecological viewpoint, color harmony might stem from ecological color statistics in natural images corresponding to different areas of the same ecological object [14]. A red sweatshirt, for example, would be darker red where it was in shadow and lighter red where it was brightly illuminated. Accordingly, pairs that are judged to be most harmonious (i.e., that “go together” best) may, in fact, be those that are most likely to co-occur within the same object in natural images.

Color Processing, Cortical

Daniel C. Kiper

Institute of Neuroinformatics, University of Zurich and Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

Synonyms

Chromatic processing; Cortical

Definition

The transformation of color signals and chromatic properties of receptive fields within the visual cortex of primates.

Processing of Chromatic Signals in the Early Visual Pathways

The processing of chromatic signals in the retina and lateral geniculate nucleus (LGN) has been the focus of numerous studies and is well understood. Less is known about the fate of color signals in the cortex. This entry first reviews central aspects of color processing in the primary visual cortex (V1) and discusses how it differs from subcortical processes. It then discusses the processing of color signals in extrastriate visual areas.

Color in the Striate Cortex (V1)

Chromatic Properties of Individual Neurons

In the primate primary visual cortex, it had been estimated that about 50% of the cell population is selective for color [1]. Estimates of the proportion of color-selective cells, however, are complicated by the use of different criteria for the classification across studies. Interestingly, color signals in primary visual cortex have long been thought to be relatively weak relative to black and white stimuli. Studies based on imaging techniques of the active human brain, however, have now clearly

demonstrated that primary visual cortex contains a large proportion of color-responsive and color-selective cells [2]. The majority of color-selective cells in V1, like those of its subcortical input, the lateral geniculate nucleus (LGN), simply add or subtract their chromatic inputs. Indeed, most V1 [3] cells' responses to chromatic modulations are well accounted for by a model postulating a linear combination of the signals derived from the three cone classes. Although there are some V1 cells that are more selective for color than predicted [4], the model adequately fits the responses of the majority of V1 cells.

The preferred colors of V1 neurons [2], however, do not cluster around the three cardinal directions found in the LGN [5]. Instead, cells often prefer colors that lie intermediate to these "cardinal" directions. For cortical cells, the classification of chromatic cells into red-green or blue-yellow opponent cells is therefore not valid anymore.

Moreover, most color-selective cells in V1 [6] respond also vigorously to luminance variations, a property that seems ubiquitous in the visual cortex. It also illustrates the fact that color selectivity does not imply color opponency. A response to stimuli containing chromatic but no luminance information (isoluminant stimuli) does not imply that the neuron receives opponent inputs from two or three cone classes. True color opponency can be deduced in neurons that give stronger responses to isoluminant than to luminance stimuli, provided that the stimuli are equated for cone contrasts [7]. It thus appears that in the cortex, there is a whole continuum of cells, ranging from strict color opponency to strict luminance [8].

Recent studies have also shown that, unlike earlier levels, primary visual cortex contains so-called double-opponent cells [6]. Double-opponent cells are cells whose receptive field combines color and spatial opponency. The defining functional property of these cells is that they respond strongly to color patterns but weakly or not at all to uniform (full-field) color modulations. The existence of pure double-opponent cells, cells with non-oriented receptive fields that respond only to color patterns [9], has been hotly debated in the last years. While early reports have been

contested, it now appears that double opponency does exist in primary visual cortex but linked with other functional properties such as orientation selectivity and a high sensitivity for luminance stimuli as well [6].

Clustering and Specialization of Color-Selective Cells in V1

In the last decades, the localization and functional specialization of color-selective cells within area V1 have been the matter of debate. A number of studies reported that color-selective cells in V1 are not orientation selective (a canonical property of virtually all primate V1 neurons) and that these cells are clustered within the cytochrome oxidase (CO)-rich blobs that have been described previously [10]. Both claims, however, have been contested by a number of anatomical and physiological studies [8]. Some of the controversy can be attributed to the different techniques and stimuli that have been used to localize and characterize color-selective cells. A number of extensive and careful studies using single-cell recordings combined with histological processing have clearly shown that color-selective cells are not restricted to the CO blobs.

The same studies have shown that color selectivity and orientation selectivity are not, as originally proposed, segregated within the V1 cell population. The most convincing, but not unique, evidence for conjoint selectivity to color and orientation comes also from single-cell recordings [11].

The Case of Blue-Yellow Signals

For a number of mostly technical reasons, many color-vision studies have focused primarily on red-green opponency and less on the evolutionary older blue-yellow system. The discovery of the koniocellular layers in the LGN and their predominant role in the processing of blue cone signals (necessary for blue-yellow opponency) [12] raised the possibility of a specialized treatment of blue cone signals within the primary visual cortex. To what extent blue cone signals are clustered within V1 and how much they contribute to cortical color processing is not clear yet. Recent studies seem to indicate that blue cone signals are

distributed uniformly within V1 (no clustering) and that these signals might be combined with achromatic signals in the double-opponent cells described above.

Color in the Extrastriate Cortex

Although several studies showed that individual neurons in the dorsal visual pathway, in particular in area MT of the macaque monkey, can significantly respond to chromatic variations [13], these responses are typically smaller than those obtained with luminance stimuli and do not account for the animal's behavioral performance. The following sections are thus restricted to areas of the ventral pathway that are known to play a critical role in color processing.

Proportion of Color-Selective Cells

In extrastriate areas of the ventral pathway, the number of neurons whose responses are affected by color variations remains surprisingly constant despite the variability of the criteria used to classify neurons. This proportion reaches 50% in area V2 and 54% in V3 [1]. Estimates in later areas of the ventral pathways (reviewed in 8) are more variable. In area V4, often but mistakenly considered a "color" area of the primate brain, original estimates ranged from less than 20–100%. A more recent estimate of 66% has been reported. In the IT cortex, it has been estimated around 48%.

Chromatic Properties of Individual Neurons

As already described in V1 neurons, the chromatic properties of extrastriate neurons differ from those in the retina and LGN in two important ways. First, a significant proportion of neurons in each area possess a high degree of color selectivity. These neurons show a narrow tuning in color space. Narrowly tuned neurons have been reported, in different proportions, within areas V2, V3, and V4. The second major difference already described in V1 concerns individual neurons' preferred colors. As in V1, the distribution of preferred colors of extrastriate neurons is not clustered in color space but is uniformly distributed [8].

Color Versus Other Visual Attributes

The question of conjoint selectivity for color and other visual attributes has been posed and answered for V1 neurons (see above). Similarly, the question whether color and other visual attributes such as orientation, motion, and size are segregated in the extrastriate cortex has been studied. Numerous studies (see [8]) in the last decade have shown that cells within V2, V3, and V4 can be concomitantly tuned for several dimensions of the visual stimulus. It thus appears that color is not processed independently but by the same neuronal populations that also code orientation or size. Note however that a recent study reported the existence of a significant subpopulation of V4 cells that respond to chromatic but not luminance variations leading the authors to suggest that color and luminance might be treated by different channels within area V4 [14].

Clustering of Color-Selective Cells

The debate concerning the organization of color-selective cells into clusters within a given area has extended to several visual areas beyond V1. In V2, the thin bands defined by CO staining have been reported to represent clusters of color-selective cells and to be the source of the color signals sent to area V4 and areas of the inferotemporal cortex. Moreover, optical imaging studies of area V2 concluded that color is represented in an orderly fashion within the thin stripes in the form of well-defined color maps that resemble those based on human color perception. As in V1, however, the clustering of color selectivity within the thin CO stripes has been challenged.

In areas more posterior within the temporal pathway, color-selective cells have been reported to cluster into subregions. This clustering is in fact often offered as an explanation for the large variance in estimates of the proportion of color-selective cells in the temporal cortex. Microelectrode recordings in dorsal V4 are thought to encounter many color clusters that seem to be much less prevalent in ventral parts of V4.

In the most anterior parts of the ventral pathways, the distinction between cortical areas is

much less clear, and the relationship between areas reported in the macaque brain with those of the human is still controversial. It has nonetheless been suggested that color might be treated within a specialized pathway that extends across several of the ventral visual areas including V2, V4, and the dorsal portion of the posterior inferotemporal cortex (PITC) [15]. Within PITC, color-selective cells would be clustered into islands themselves containing orderly, columnar color maps, reminiscent of the organization previously reported in V2.

Is There a Color Center in the Primate Brain?

Several of the issues discussed above are intimately related to the question whether the primate brain contains one color center, a cortical area whose main function would be to support most or all aspects of color perception. The notion of a color center is a natural consequence for the proponents of a strictly modular view of cortical organization. Most researchers agree that there are areas in the ventral cortex that are highly activated by color stimuli, but none of these areas have been established as predominant over the others.

Moreover, experimental lesions in macaque V4, the most popular candidate for the role of color center, do not result in a complete loss of color vision. These results cast doubts on the notion of a unique color center and support the idea that color, like many other visual attributes, is treated within a network of neuronal populations distributed within the ventral occipitotemporal pathway.

Unresolved Issues

Important perceptual phenomena such as color constancy, unique hues, or color categorization remain largely unexplained. Further studies reconciling imaging or lesion results in the human brain with those obtained by methods revealing single activity in the macaque brain are thus necessary to fill these gaps. Moreover, the relationship between color signals and those associated with other visual attributes such as object shape or

motion needs further scrutiny, particularly in extrastriate areas. Today, it is safe to say that a full understanding at the neuronal level of perceptual phenomena associated with color is still eluding the vision science community.

Color Psychology

Zena O'Connor

Design Research Associates, University of Sydney, Sydney, NSW, Australia

Synonyms

[Chromotherapy](#); [Psychological impact of color](#)

Definition

Color psychology refers to a branch of study which postulates that color has a range of psychological or behavioral responses.

Overview

Color psychology and color therapy exist on the periphery of alternative medicine and are generally not accepted under the auspices of mainstream medical science and psychology. Despite this, a plethora of articles can be found in mainstream and digital media that discuss a link between color and a range of psychological, cognitive, biological, and behavioral effects. While it is often promoted that such a link exists on a universal, causal basis by some sectors of the media, there is minimal evidence to support this hypothesis. Furthermore, there are a number of factors that influence color and human response, and these include individual differences (such as age, gender, affective state, belief systems, and

environmental stimuli screening ability), social and cultural differences, as well as contextual and temporal differences. Despite this, claims such as *red is stimulating and arousing* and *blue is calming, relaxing, and healing* are often quoted without substantiation or evidence of any nature in popular media. The source of such claims can be traced to a number of key authors including Faber Birren, Kurt Goldstein, Robert Gerard, and Max Lüscher, whose works have been either superseded or debunked for lack of scientific rigor. However, some proponents have a vested interest in promoting a link between color and human response due to the popularity of such claims and the opportunity to capitalize on this popularity through the sale of books, workshops, courses, and consultancy services. While there is a place for such products and services, there are also compelling reasons to apply the principle of caveat emptor to color psychology and color therapy claims found in nonacademic sources.

Defining Color Psychology

The term “color psychology” suggests that the interface between color and human response is underpinned by a causal link wherein color has the capacity to influence a range of human responses including affective, cognitive, and related behavioral responses. In mainstream media and popular culture, “the psychological effects of color” is assumed to be a causal link that exists on a universal basis irrespective of individual differences or the impact of cultural, contextual, or temporal factors [1, p. 9]. This understanding about color psychology remains fairly consistent; however, some sources extend the definition to include a larger gamut of responses from ► [color preference](#) to precognitive, psychophysical, and “biology-based responses,” defined as responses on human metabolism, circulation, and respiratory systems [2, p. 92].

The word “therapy” as in “color therapy” generally refers to a remediation of a health or psychological issue intended to address a diagnosed problem or stop a medical or psychological condition from occurring. Hence, color therapy implies that color can be used as a therapeutic

device in the remediation of a health or psychological issue. Some writers take this concept further and suggest that the “biological consequences of color responses can be a valuable tool in health management” for the treatment of various ailments, and this appears to be a fairly common understanding of the term [2, p. 93], while other writers suggest that color therapy, or chromotherapy, can be used prescriptively as a “truly holistic, non-invasive and powerful therapy which dates back thousands of years” [3, p. 1].

The Interface Between Color and Human Response: Recent Research

Academic literature includes a broad range of studies that discuss the effects of light as well as the influence of colored light waves in respect to human response. While human vision is a complex and not yet fully understood process, the receptor system for detecting light has been found to be different from that associated with the circadian cycle [4]. In reference to human circadian cycles, light tends to regulate our sleeping patterns and changes in light–dark exposure can desynchronize the circadian cycle affecting the ability to sleep and wake, as well as impacting on physiological and metabolic processes. Disruptions to the circadian rhythm may result in changes in mood and behavior as evidenced by studies that focus on seasonal affective disorder, known by the acronym SAD (seasonal affective disorder) [5–7]. Light has also been found to have an effect on the human neuroendocrine system and may also suppress melatonin and elevate cortisol production, which can have negative impacts [7, 8]. Furthermore, a number of recent studies have indicated that certain wavelengths of light may have specific impacts. For example, blue light may improve cognitive performance; different colored lenses may assist with reading difficulties such as dyslexia; and the human circadian system may be particularly sensitive to short-wavelength light [9–11]. Despite the many advances in recent research, the precise roles of the rods and cones of the retina as well as melanopsin in the control of circadian cycles remain to be determined [12].

A plethora of studies exist which suggest that color may influence a range of psychological, physiological, and behavioral responses; however, the range and diversity of research findings was highlighted by an analysis of 30 studies [13]. For example, it has been suggested that red has a greater capacity for arousal than blue [14–16]. However, findings from a more recent study suggest that there is no statistically significant difference between these two colors in terms of physiological arousal and that it may be hue rather than saturation (intensity) of color that has an impact [17]. In addition, recent studies have found that responses to color may vary depending on age, gender, culture, and preference [18, 19]. It is important to note that while many of the recent studies that focus on psychological, physiological, and behavioral responses are scientifically rigorous, the findings are often based on an extremely limited range of color samples or a small sample group. In terms of color therapy, while associations may exist between various colors and a range of different human responses, it does not necessarily follow that such colors can be effectively used in therapy as some sources in popular media suggest.

Color Psychology in Popular Media

Information about color psychology in popular media is abundant and accessible via myriad magazines, online magazines, and Internet websites. Internet search engine Google currently provides access to 365,000 websites for information relating to color psychology. For example, www.colorthrapyhealing.com provides numerous pages on color psychology and color healing, respectively, including fairly detailed information about the use of color as a therapeutic tool and a range of color therapy workshops. Similarly, www.colour-affects.co.uk offers detailed comment about the so-called psychological properties of color and provides a summary of four personality types supposedly linked to specific colors. In addition, mass media magazines and online magazines such as *WellBeing* (www.wellbeing.com.au) feature various articles on color psychology and color therapy.

The information available from popular, mainstream media can vary from broad, generalized commentary to detailed, pseudoscientific discussions peppered with relatively harmless generalizations, platitudes, and motherhood statements, at best, and unsubstantiated and highly dubious claims, at worst, such as “colors are the mother tongue of the subconscious” and “color heals.”

Some sources of information provide claims about perceptual color effects and color associations intermingled with unsubstantiated claims about color psychology such as:

Although red, yellow and orange are in general considered high-arousal colours and blue, green and most violets are low-arousal hues, the brilliance, darkness and lightness of a colour can alter the psychological message. While a light blue-green appears to be tranquil, wet and cool, a brilliant turquoise, often associated with a lush tropical ocean setting, will be more exciting to the eye. The psychological association of a colour is often more meaningful than the visual experience.

Colours act upon the body as well as the mind. Red has been shown to stimulate the senses and raise the blood pressure, while blue has the opposite effect and calms the mind.

People will actually gamble more and make riskier bets when seated under a red light as opposed to a blue light. That's why Las Vegas is the city of red neon. [20]

Other sources of information suggest that color has therapeutic effects such as the claims provided in the online magazine *Conscious Living*.

Colour can repair and heal the body, when the frequency of the colour aligns with the emotion needed to activate the micro-particulars so healing can take place. . . The use of colour in visualisation is most effective, and easiest for the novice to utilise, as colour has a very strong radiating effect on the whole body. Every other form of colour therapy is fundamentally symbolic. [21]

In a similar vein, Wright suggests that

In practice, colour psychology works on two levels: the first level is the fundamental psychological properties of the eleven basic colours, which are universal, regardless of which particular shade, tone or tint of it you are using. Each of them has potentially positive or negative psychological effects and which of these effects is created depends on personality types and —crucially— the relationships within colour combinations, the second level of colour psychology. [22]

Wright offers further clarification from the colour affects system, and it should be noted that the colour affects site offers color consultancy services plus a range of industry and personal courses and workshops.

Similarly, Rewell provides a detailed discussion about specific responses to color in the online magazine *WellBeing* as follows:

Babies cry more in yellow rooms. Tension increases in people in yellow rooms and people who drive yellow cars are more prone to become aggravating in heavy traffic... Spend time exposed to a lot of yellow and you'll feel like time has sped up... A rejection of yellow indicates a fear of change... Red stimulates the physical and adrenalin. It raises blood pressure, the heart rate and respiration. [23]

Other sources of information about color psychology include architectural and interior design books (e.g., see Kopacz and Mahnke) as well as technical reports [2, 24, 25]. In addition, various courses and workshops discuss issues relating to color psychology including the Colour Therapy Healing organization in the UK, the International School of Colour and Design in Sydney, and the Nature Care College in Sydney [26–28].

Information from sources such as those discussed above often quotes a range of color associations co-mingled with various psychological, cognitive, or behavioral responses to color. In addition, such sources rarely if ever provide evidence to substantiate any claims regarding the impact of color on human response. An example of the intermingling of a range of different types of response is provided by Cherry as follows:

Red is a bright, warm color that evokes strong emotions. Red is also considered an intense, or even angry, color that creates feelings of excitement or intensity.

Blue calls to mind feelings of calmness or serenity. It is often described as peaceful, tranquil, secure, and orderly. Blue can also create feelings of sadness or aloofness. Blue is often used to decorate offices because research has shown that people are more productive in blue rooms.

Green is restful, soothing, cheerful and health-giving. Green is thought to relieve stress and help heal. Those who have a green work environment experience fewer stomach aches. Green has long been a symbol of fertility. [1]

Some sources go so far as to state symbolic color associations and then extend these further to include different situations or contexts such as the following:

Red is the colour for courage, strength and pioneering spirit... It is the colour of anger, violence and brutality.

Blue is calming, relaxing and healing (but) not as sedentary as indigo.

Green is the colour of balance and harmony and can, therefore, be helpful in times of stress. If one has experienced trauma, a green silk wrapped around the shoulders can have a very therapeutic effect. [3]

It is not uncommon for claims such as those above to be presented in an authoritative manner, exhorting the reader to believe and accept; however, the lack of evidence indicates that such claims are often personal opinion masquerading as scientific fact or pseudoscience.

An Irrefutable, Causal, and Universal Link Between Color and Human Response?

Various sources of information in mainstream media and related sources tend to suggest that an irrefutable, causal relationship exists between color and human response, as illustrated by Hill's statement: "Based on numerous studies by Drs Morton Walker, Gerard and Faber Birren, the link between color and physiological responses has been well documented" [24, p. 7].

In addition, many sources imply that the link between color and human response is universal irrespective of individual or cultural differences. For example, Logan-Clarke asserts: "Red... is stimulating and energizing therefore it is helpful for tiredness and lethargy, to stimulate low blood pressure, to boost sluggish circulation... Red is energizing and excites the emotions, and can stimulate the appetite" [3, p. 10]. Similarly, Rewell contends "Red stimulates the physical and adrenalin. It raises blood pressure, the heart rate and respiration" [23], while Kopacz suggests "Red is believed to sensitise the taste buds and sense of smell, increasing the appetite... all this occurs because the heart rate instinctively quickens, which causes a release of adrenalin into the bloodstream raising blood pressure and stimulating the nerves" and "the sight of the color blue causes the

body to release tranquilizing hormones when it is surveyed, particularly a strong blue sky” and “many believe (blue) can lower blood pressure, slow the pulse rate and decrease body temperature” [2, pp. 76, 79].

In regard to such claims, Kopacz notes the lack of evidential support but offers the work of a number of authors and designers including Birren and Mahnke as well as Morton Walker (author of *Bald No More, Foods for Fabulous Sex, Your Guide to Foot Health*, as well as *The Power of Color*) and Wright (color consultant of www.colour-affects.co.uk) to support his color psychology claims. Similarly, Mahnke notes the inconclusive nature of findings from research that focuses on the interface between color and human response, but nevertheless refers to the work of Birren and Goldstein among others as support for various psychophysiological effects of color.

In regard to color therapy, it is suggested that color can be used as a treatment tool in conjunction with the seven chakras of the body [2, 3, 25]. The concept of chakras, considered to be energy centers within the human body, belongs to a belief system originating in the Hindu scriptures known as the Upanishads, dating from the first millennium BCE. Under the color chakra theory, a color is linked to each of the seven chakra and these colors are associated with bodily functions and dysfunctions within each chakra area. For example:

Red: Activates the circulation system and benefits the five senses; used to treat colds, paralysis, anaemia, ailments of the bloodstream and ailments of the lung;

Blue: Raises metabolism; is used to stabilize the heart, muscles and bloodstream; used to treat burns, skin diseases, glaucoma, measles and chicken pox, and throat problems;

Green: Strengthens bones and muscles, disinfects bacteria and virus, and relieves tension; used to treat . . . malaria, back problems, cancer, nervous disorders, and ulcers, and to manage heart problems and blood pressure. [2, p. 93]

The allocation of colors to each of the chakras is reminiscent of the doctrine of the four color-linked humors of the body from ancient Greek medicine: black bile, yellow bile, green phlegm,

and red blood. The linking of color with the humors, the four elements (earth, fire, water, and air) as well as the seasons, represented the color correspondence beliefs that emerged in antiquity and continued through to the Renaissance as evidenced by the color correspondences depicted in the engraving by Nicoletto Rosex [29].

Aside from ancient belief systems, much of the information currently available in popular media about color psychology echoes, if not directly quotes, the work of a number of key theorists, including Faber Birren, Robert Gerard, Kurt Goldstein, and Max Lüscher (e.g., see [1–3, 22, 25, 30–32]).

Birren, Gerard, Goldstein, and Lüscher

Extensively quoted by recent authors, Birren published more than 40 books and over 250 articles on color psychology, color therapy, as well as color application. Tunney advises that Birren was a leading authority on color in the mid-twentieth century who was retained as a color consultant by DuPont, General Electric, Sears, Roebuck and Company, and the United States Navy [33]. Birren championed an unambiguous, irrefutable, and universal causal link between color and human response, and he cites Goldstein’s assertion that “It is probably not a false statement if we say that a specific color stimulation is accompanied by a specific response pattern of the entire (human) organism” [34, p. 144]. Given his role as color consultant, it was in his interests to champion such a link as he was able to then provide advice addressing this link in a range of commercial contexts.

Goldstein, who published *The Organism* in 1939, was considered a significant authority on the psychological and physiological impacts of color by Birren, who quoted Goldstein in his *Color Psychology and Color Therapy* publication: “under the influence of red light, time is likely to be overestimated. Conversely, under the influence of green or blue light, time is likely to be underestimated” and “under red light, weights will be judged as heavier; under green light they will be judged lighter” [35, p. 211]. Birren as well Mahnke cites Goldstein’s 1942 study, which

discussed the perceived stimulating effects of red and the opposite effects of green [16].

Gerard, whose 1958 doctoral thesis (“Differential effects of colored lights on psychophysical functions”) was subsequently presented as a conference paper (“Color and emotional arousal”), is also frequently cited by Birren and Mahnke [15, 36]. Gerard’s key findings from his study on the arousal properties of red, blue, and white illumination, as reported by Wise, Wise, and Beach, include: “statistical differences between red-blue (illumination) conditions for all physiological measures except heart rate. . . responses to the white light varied but most often were similar to those of the red condition” [37, p. 5]. Wise et al. also note that Gerard, whose study involved a small sample of only 24 male university students, advised caution in terms of the generalizability of his findings. It is unfortunate that Gerard’s advice was not reported by subsequent authors.

Lüscher, who developed and published the Lüscher Color Test, included four basic colors (which he referred to as psychological primaries) in the color test: orange-red, bright yellow, blue-green, and dark-blue, as well as four auxiliary colors – violet, brown, black, and neutral gray [38]. Citing anecdotal evidence, Lüscher assigned specific associations and affective characteristics to each color. For example, (red) has a “stimulating effect on the nervous system – blood pressure increases, respiration rate and heartbeat both speed up”; while blue “has the reverse effect – blood pressure falls, heartbeat and breathing both slow down” [38, p. 12]. The Lüscher Color Test is essentially a ► [color preference](#) test and its use in personality testing and assessment has been soundly cautioned [39].

While the works of Birren, Gerard, Goldstein, and Lüscher have their place in the literature on color, it is important to note that their theories have, to a large extent, been debunked due to methodological shortcomings. In addition, more recent and methodologically more rigorous studies have superseded these earlier authors, and this, plus a number of other reasons discussed below, provides a compelling case for applying the principle of caveat emptor to information about color

psychology and color therapy found in mainstream media.

Color Psychology and Color Therapy: Caveat Emptor

Latin for “buyer beware,” the term caveat emptor suggests that in the absence of a warranty, the buyer is at risk, and therefore onus for carefully assessing goods and services prior to purchase remains with the buyer. O’Connor suggests there are a number of reasons why the principle of caveat emptor should prevail in regard to information about color psychology and color therapy [50].

Firstly, the existence of an irrefutable and universal causal link between color and an unlimited range of psychological, biological, and behavioral responses remains a largely unsupported hypothesis. While numerous studies exist that focus on the interface between color and human response, a systematic and critical review of over 200 studies was conducted for the National Aeronautics and Space Administration (NASA) in 1988. This study concluded that “there are no ‘hard-wired’ linkages between environmental colors and particular judgmental or emotional states” [37, p. 46].

In addition, while a number of studies exist which focus on the interface between color and human response, the findings of many of these studies are limited by the setting and context of the study, the size and composition of the sample group, as well as the limited range of colors used in the stimuli. Extrapolating beyond the data in such studies is methodologically unsound, especially when small sample sizes are used [40]. Very small sample groups were used by many early studies including the often-quoted studies of Goldstein and Gerard:

- Sample size of 3–5 [16]
- Sample size of 24 [15]
- Sample size of 48 [41]
- Sample size of 14 [42]
- Sample size of 25 [43]

In addition, many early studies focused on the color attribute of hue alone without any consideration of the attributes of tonal value or saturation, and many research studies used small colored

squares of cardboard as stimuli and the findings from such studies were extrapolated to a whole range of other contexts or situations. The findings of such studies have extremely limited relevance due to the methodological weakness of studying a complex and highly subjective phenomenon as color in isolation with limited stimuli.

Ancient wisdom is often cited as a reason to believe claims about color psychology and color therapy, with the underlying logic implying that ancient wisdom embedded within such claims represents evidential proof. For example, Kopacz cites the link between color and chakras of ancient Hindu scriptures as evidence, while Van Wagner suggests that chromotherapy was practiced by ancient cultures, including the Egyptians and Chinese [1, 2]. Such authors imply that not only is the wisdom of the ancients above question but it provides evidential proof of the veracity of various color-related claims. Clearly, ancient belief systems are not always a guarantee of veracity as evidenced by the superseded beliefs that the world is flat, and the sun and moon orbit the earth. Without disparaging the wisdom of the ancients, it is a fair comment that a proportion of ancient wisdom has been superseded by later scientific discovery. The existence of a link with ancient wisdom should not of itself be used as evidential proof of any claim regarding color psychology and color therapy.

Factoids are not facts, although many authors who write about color psychology and color therapy would have us believe otherwise. Coined by author Norman Mailer, factoids are suppositions or inventions presented as fact, and a comedic illustration is the line in the film *Anchorman*: "It's anchorman not anchor-lady, and that's a scientific fact!" [44]. Color psychology and color therapy information available in popular culture often appears as factoids rather than facts, especially when nil evidence is cited to support claims and assertions. Examples of unsubstantiated factoids include: "We are hard-wired to yellow as a stimulus. . . If you're environment is boring and time passes slowly, surround yourself with small amounts of yellow" and "People who dislike yellow often favour blue to calm themselves and feel

secure. If you drink coffee for a pick-me-up, try drinking it from a yellow cup" [23, p. 32]; similarly, "Yellow can also create feelings of frustration and anger. While it is considered a cheerful colour, people are more likely to lose their tempers in yellow rooms and babies tend to cry more in yellow rooms" [1].

The use of control groups, measures to control internal and external validity, and adequate levels of statistical significance are absent from some studies that focus on the interface between color and human response, and these impact negatively on the scientific rigor of such studies. It is empirically and methodologically unsound to draw generalized conclusions from such studies and transfer them to different settings and contexts [40, 45–47].

The fallacy of the single cause provides another reason to be cautious about claims regarding color psychology and color therapy. This fallacy suggests that one single cause for an outcome represents causal oversimplification, and under the post-positivist paradigm, recent theorists such as Hård and Sivik consider the interface between color and human response to be highly complex and open to the influence of a wide range of factors and mediating variables [48]. While correlation may indicate the existence of an association between one variable (such as color) and human response, correlation does not imply causation and suggesting a causal link without allowing for mediating variables is considered empirically and methodologically unsound [40, 45, 47].

Inherent bias, subjective validation, and data cherry picking in research studies always call into question the findings of such studies [40]. Specifically, "Scientists have a vested interest in promoting their work," and this is often the case for color theorists and researchers whose publications support their role as consultants [40, p. 337]. In addition, subjective validation is evident in many studies that focus on the interface between color and human response. This occurs when two unrelated events are judged to be related because of an expectation of such or because an existing hypothesis demands such a relationship. For

example, to apply the notion that “green relieves stress” to the following claims: “green silk wrapped around the shoulders can have a very therapeutic effect” and “Those who have a green work environment experience fewer stomach aches” indicates subjective validation and renders such claims invalid.

It is unwise to ignore any mediating variables that may impact a research study and this is particularly relevant to research that focuses on the interface between color and human response. In this context, mediating factors include an individual’s personality, personal bias and feelings, as well as cultural experiences and affective state. Mehrabian found that individual differences exist in terms of stimulus screening ability, and high screeners are able to automatically screen out less important components of environmental stimuli such as color and sound as opposed to low screeners [49]. Stimulus screening ability is rarely if ever mentioned in research studies that focus on color and human response nor is an individual’s own bias in terms of whether or not they consider color to have an impact on their responses to color.

To conclude, color psychology claims information found in mainstream media suggests that color prompts a range of different human responses: psychological, biological, and behavioral. Many of these claims lack substantiation in terms of empirical support, exhibit fundamental flaws (such as causal oversimplification and subjective validation), and are generally personal opinion and factoids masquerading as fact. Color psychology is a discipline that is not accepted within the medical profession and exists on the periphery of alternative medicine and therapies. It is therefore recommended that the principle of caveat emptor is applied when evaluating information about color psychology plus check with a medical practitioner or psychologist before acting upon such information.

color distribution; Natural scene statistics

Definition

Color scene statistics or chromatic scene statistics are statistical characteristics of scene color. There are a number of ways to analyze color scenes (natural scenes) statistically in relation to vision, such as the average color, color distribution, Bayesian model, principal component analysis, and probabilistic models. Color scene statistics are closely related to the evolution and development of the color vision mechanism at every level of the visual system.

Overview

Color vision has evolved with the natural environment, including the natural illumination from the sun and the sky. Thus, the color statistics of a natural scene must have an enormous impact on the evolution and development of the color vision mechanism. There have been many attempts to analyze natural scene statistics and find the connection to the color vision mechanism as well as other aspects of the visual mechanism.

Traditionally, the average color and color distribution of a scene are associated with color adaptation and color constancy. Based on those statistical data, physiological, empirical, and statistical models of color constancy were introduced. Other aspects of visual perception, such as color discrimination or color appearance, would be formed by the environment to obtain the best performance or representation under a given color environment. Measurement techniques, such as two- and three-dimensional measurements of scenes and multispectral measurement, provide additional information for deeper analysis or analysis from different perspectives. Powerful computational analyses introduce new statistical approaches for investigating the mechanism of color vision. Here, the topics of color scene statistics related to color vision, visual perception, and their evolution are discussed.

Measurement of Objects, Illumination, and Scenes

Obtaining accurate color information of scenes is important to analyze color scene statistics. Camera calibration techniques and calibrated images in which the RGB values of images are transferable to information on chromaticity coordinates have been developed.

Another important aspect of analyzing colors in natural scenes is spectral information. RGB information has only three dimensions, and consequently, some information is lost. For instance, RGB information cannot differentiate metameric color, which results when a pair of stimuli exhibit the same apparent color but with different spectral power distributions. Many groups have measured the daylight spectra and spectral reflectance of natural and printing surfaces. Published databases (e.g., SOCS [1]) and personal databases on websites are available.

For obtaining the spectral color information of an entire scene, multispectral or hyperspectral image capture techniques using a multispectral camera are used. Those data are used for studies on color vision mechanisms. It is difficult, however, to obtain a hyperspectral image manually because it

takes a long time, and the scene must be still (no moving objects or wind) to capture an image with multiple wavelengths by changing band-pass filters. Therefore, collections of multispectral images of outdoor scenes are limited [2]. The recent development of fast and accurate multispectral cameras will allow further statistical analysis based on a large number of multispectral data sets.

Although multispectral information is important and useful, it includes a massive amount of data that is inconvenient to handle. Thus, there have been many attempts to represent multi-dimensional data with a smaller number of

dimensions by compressing the amount of information using principal component analysis (PCA). The natural spectra can be represented well by three basis functions. Those for the illuminant obtained by Judd [3] are shown in Fig. 1. The basis functions give the relative spectral radiant power distribution of the CIE daylight illuminant at different color temperatures (Fig. 1a). Cohen [4] applied this analysis to the reflectance of Munsell color paper and showed three basis functions that were different from those obtained by Judd. Later studies suggested that Cohen's data were applicable to natural surfaces (see Fig. 1b)

Color Scene Statistics, Chromatic Scene Statistics, Fig. 1 Examples of three basis functions for daylight (a) and reflectance (b), respectively. A Gaussian fitting function

with three parameters: peak, amplitude, and bandwidth (for both illumination and reflectance) is also shown (c)

and that three basis functions were necessary and probably sufficient for representing the spectral reflectance functions of natural objects. (Note that some studies suggested that a larger number of basis functions are needed depending on the context.) These results led to the hypothesis that the human visual mechanism has a similar representation in the visual process [5]. However, it was recently suggested that the Gaussian fitting function with three parameters: peak, amplitude, and bandwidth to natural spectra (see Fig. 1c) is as good as the fitting by three basis functions [6]. More investigations would be needed to determine how the human visual system represents the spectral world.

Analysis of Natural Color Statistics

There are a number of ways to analyze the color properties of a scene statistically. The most basic method would be by average color and color distribution. Analysis taking into account spatial frequency is also important because the spatial contrast sensitivities of luminance and the L-M (reddish–greenish) and S-(L + M) (bluish–yellowish) opponent-color channels are different. Those chromatic channels tend to have a low-pass shape, suggesting the low-frequency component contributes more to color perception. Recent developments in statistical modeling, along with powerful computational tools, have enabled researchers to study more sophisticated statistical models of visual images and to evaluate these models empirically against large data sets [7].

Based on the information obtained from color scene statistics, the mechanisms of vision and color perception have been investigated from aspects of the peripheral to central visual system to perspectives on evolution, development, and short- to long-term adaptation, as described in the following sections.

Effect on Evolution of Color Vision

The sensitivity of the photoreceptors and how the cone signals are combined in postreceptoral

channels have been explained by assuming that they optimize the efficient coding of natural color signals and that they are tuned to specific signals.

For example, it has been suggested that trichromacy in Old World primates and the reflectance functions of tropical fruits coevolved and that primate color vision has been shaped by the need to find reddish (ripe) fruit or young (edible) leaves among green foliage, as shown by the example in Fig. 2. For instance, the tuning of the L and M cones and the later opponent-color system (L-M) based on the signal representing their difference are optimized to detect the color signals provided by ripening fruit or edible foliage [8]. This hypothesis is a good example of how color statistics of the visual environment

Color Scene Statistics, Chromatic Scene Statistics, Fig. 2 Examples of the advantage of trichromacy (*top*), capable of red–green discrimination, compared to dichromacy (*bottom*) on finding red fruits among green leaves

Color Scene Statistics, Chromatic Scene Statistics, Fig. 3 An example of seasonal changes in the natural color scene (Mountain forest in the Sierra Nevada) and the average chromaticities for earth (large symbols) and

sky (small symbols) for individual scenes plotted in the Macleod-Boynton color space. b axis represents $S/(L + M)$, r axis represents the $L/(L + M)$

affected the early-stage evolution of the color vision system.

It has also been shown that seasonal variations in the color statistics of natural images alter the average color in scenes, as shown in Fig. 3. The average chromaticities for earth and sky for individual scenes in the Macleod-Boynton color space indicate that large seasonal color shift along b (+ L) direction. Color distribution in scenes also changes across seasons. On opponent-color space, arid periods are marked by a mean shift toward the + L pole of the L - M chromatic axis. A rotation in the color distributions away from the S -($L + M$) chromatic axis and toward an axis of bluish–yellowish variation, both primarily due to changes in vegetation. These data imply that systematic color changes in season contribute to the construction of the mechanism of both visual sensitivity and color appearance [9].

There are other hypotheses, such as skin tone discrimination and predator detection affecting evolution. There are a number of variations or changes in natural environments other than the examples shown above, which may contribute to the formation of the color vision mechanism. It is interesting to pursue how the color vision mechanism was optimized during evolution and development [10].

Cortical Mechanism and Probabilistic Approaches

Cortical color coding is also thought to have evolved to represent important characteristics of the structure of color in the environment. Probabilistic modeling allows us to test the efficient coding hypothesis for both individual neurons and populations of neurons experimentally [7].

“Sparse coding,” the concept that neurons encode sensory information using a small number of active neurons at any given second, has been introduced. It increases the storage capacity of associative memories and saves energy. It also makes the structure of natural signals explicit and makes complex data easier to interpret during visual processing [11]. They created a model based on a linear superposition of basis functions. They adapted these functions to maximize the sparsity of the representation while preserving information in the images by maintaining a bound on the mean squared reconstruction error. Function sets that emerge after training on numerous image patches randomly extracted from natural scenes resemble the spatial receptive field properties of simple cells (i.e., spatially localized, oriented, and band-pass in different spatial frequencies). Figure 4 shows an example of a set of basis functions

Color Scene Statistics, Chromatic Scene Statistics, Fig. 4 An example of sparse coding created by a procedure by the method in the paper of Olshausen and Field [11]. *Top*, image-set for learning; *Bottom*, derived basis functions

derived from a set of learning images, including natural and man-made scenes, based on a sparse coding model. Although this is only a rough example based on the limited number of images, it shows that any natural image (scene) can be constructed using combinations of basis functions. This suggests that the human visual system also constructs the image of a natural scene based on the

activity of neurons having receptive fields with different properties.

Probabilistic models are also applied to the chromatic structure of natural scenes. Independent component analysis (ICA) has been applied not only to gray images but to natural color images to establish an efficient representation of color in natural scenes. It was shown to produce

achromatic and color-opponent basis functions as well as spatiochromatic independent components that resemble cortical neurons [12]. This suggests a relationship between statistics of natural scenes and cortical color processing.

Effect of Color Statistics of a Scene on Color Constancy

Color constancy is a phenomenon in which the stability of the color appearance of an object's surface is maintained among variations in the illuminating environment. The central issue is always how humans separate illumination and the surface of objects, which is a necessary task for achieving color constancy. Identical to other mechanisms in earlier stages of the visual system, color constancy is also associated with the color statistics of environments [5, 10, 13].

A classic approach is the von Kries adaptation. To set a neutral point (or illumination color) for applying the von Kries adaptation, many assumptions or hypotheses based on scene statistics have been proposed (e.g., the average color of a scene: the gray world assumption). In Bayesian decision theory, which is a more statistical approach, the most likely combination of illuminants and surfaces is determined based on prior distributions that describe the probability that particular illuminants and surfaces exist in the world.

Characteristics of scene statistics also contribute to color constancy [13, 14]. One question is how humans can tell the difference between a white paper under red illumination and a red paper under white illumination if the papers have the same chromaticity. It was suggested that the luminance of the white paper decreases statistically under the red light and that this relationship could be a clue for differentiating the two. Besides, in natural scenes, chromatic variations and the luminance variations aligned with them mainly arise from object surfaces, such as the border between different materials. In contrast, pure or near-pure luminance variations mainly arise from inhomogeneous illumination, such as shadows or shading. The human visual system uses these color–luminance relationships and

determines the three-dimensional structure of a scene from the natural relationships between color and luminance in the visual scene, material surface, and so on. It is suggested that natural scene statistics could also be the universal basis of color context effects, such as color contrast and color assimilation.

Adaptation to the Color of Natural Scenes

As shown in color constancy, it is well known that color perception adapts to the hue change of color distribution. Color appearance is also influenced by the saturation or variance of the color distribution of a scene. A pale color patch appears less colorful when surrounded by saturated colors, and chromatically selective compression along any direction of chromatic variation occurs after adapting to temporal color variation. These suggest adaptation to the specific color gamut within individual scenes and natural environments [10, 13]. It is also shown that the impression of a natural image shifts to being less colorful after adaptation to a series of saturated images and vice versa [15]. Moreover, it is suggested that simple statistics, such as the color distribution itself, cannot explain the effect because the adaptation is stronger for natural images than shuffled images, as shown in Fig. 5. It implies the contribution of higher-level mechanisms, such as scene recognition or cognition.

The timescale of adaptation varies. It can be seconds, minutes, hours, months, years, and possibly a lifetime. The tuning of sensitivities of the color vision mechanism likely continues in all timescales. The evolution and development of the visual function could be considered a very long-term adaptation. It is also suggested that more cognitive or social aspects of color perception, such as color category, could be influenced by the color scene statistics of each region. One of the functional meanings of adaptation would be compensating for variations within an observer and between observers, as well as within an environment and between environments, to maintain a stable and coherent color appearance. The color

Color Scene Statistics, Chromatic Scene Statistics, Fig. 5 An example of natural and shuffled images used for the colorfulness adaptation experiment [15]

scene statistics certainly contribute to it. The adaptation shaped by environmental pressure would achieve an efficient transmission and stability of information from the periphery of the visual system to the centers of the brain.

Definition

An organized selection and arrangement of colors in design.

Introduction and Classification of Color Schemes

Colors from the color circle are usually combined in a systematic and logical manner to create a color scheme. The number of colors (different hues, saturations and lightnesses) in a scheme could range from two to many. A very basic color scheme would be to use black text on a white background, a common default color scheme in Web design.

A predetermined design idea about the final appearance of two-dimensional designs or products or the ambiance or atmosphere in interiors usually shapes the systematic or logic behind combining different colors into establishing a

color scheme. Creating style and appeal, evoking intended feelings (such as in an ambiance), and establishing more practical outcomes all are concerns while deciding on a color scheme.

Different types of schemes are used. These are predominantly based on the selection of colors that are regarded as being harmonious, in other words are aesthetically pleasing when viewed together. This can either be achieved with similarities or with contrasts [1, 2]. As color has three dimensions, namely, hue, saturation, and lightness, color schemes might use colors with similar hues, saturations, or lightnesses, as well as colors with contrasting hues, saturations, or lightnesses.

Color Schemes Using Harmony of Similarities

These schemes use similarity of hues (namely, monochromatic and analogous color schemes), similarity of saturations, or similarity of lightnesses. Monochromatic color schemes use a single hue and obtain a variety of colors with variations in that single hue's saturation and/or lightness levels. For example, in a room, a monochromatic color scheme may use only a certain blue with all its varying lightnesses and darkneses (lightness level) or its paler and vivid (saturation level) versions. Analogous color schemes use neighboring hues in a color circle [3]. The hues chosen in this scheme may incorporate secondary hues (hues that can be produced by adding two primary hues) such as using green, yellow-green, and yellow together. There are also warm or cool color schemes. These schemes either use all warm hues (e.g., red, orange, yellow) or all cool hues (e.g., blue and green) together.

Schemes using similarity of lightnesses combine different hues with similar lightness levels. For instance, they use only light colors together or only dark colors together. Similarities of saturations might also be used where only weak colors or only pure, vivid colors are combined together. In achromatic color schemes, only achromatic colors (black, white, and grays) are used. In this case if the design or space becomes monotonous, sometimes an accent color is added to these schemes, such as a red or a yellow.

Color Schemes Using Harmony of Contrasts

These schemes use contrasts of hues, contrasts of saturations, or contrasts of lightnesses [4]. Schemes with contrasting hues use opposite hues on the color circle. There are different complementary contrast color schemes depending on the desired number of hues to be used, namely, complementary contrast color schemes (two hues), split-complementary color schemes (three hues), double-complementary color schemes (four hues), etc. Complementary contrast color schemes use two opposing hues on the color wheel, for example, purple and yellow or red and green. These two hues can be used in the design with their many varying lightnesses or saturations. The name complementary contrast derives from afterimage complementaries, where the human visual system tries to compensate the overexposure of a certain hue with its opposing hue in the visual system [5]. When one looks at red for a few minutes, where red is the one and only thing in that person's visual field, and then that person looks at a white surface, that person will see an afterimage of the opposing hue (a light green) on that white surface. Split-complementary color schemes use not the direct opposite hue of a selected hue, but its immediate two neighbors. For example, blue will be used not with its exact opposite orange, but its two immediate neighbors which are yellow-orange and red-orange. Double-complementary color schemes use four hues, mainly two hues next to each other and their direct opposites on the color circle. Thus, yellow and yellow-orange are used together with purple and purple-blue. Triadic color schemes use hues that are evenly spaced around the color wheel, thus having equal number of hues in between them, such as using green, orange, and purple in a design.

Schemes using contrast of lightnesses use light and dark colors together, and schemes using contrast of saturations use weak and strong colors together. It is also possible to create a color scheme by using achromatic and chromatic colors together.

As there are many colors that human beings can see which can come together in many different combinations as described earlier, the initial

intent of the design or the design idea becomes prominent before deciding on the color scheme. The color scheme is chosen usually to best reflect the design intent or the design idea. This design intent or idea may vary from being fully functional to purely aesthetic. Some common design intentions are evoking an emotion, hiding from vision (camouflage), making something visible, or coding. If the design intent is to evoke an emotion, for example, creating a calming ambience, and the design idea is connotations with nature, the color scheme for a place might use similarity of lightnesses and saturations, with hues such as brown, green, and blue. If the design intent is to make things visible, for example, for visually impaired people, then the designer should not use schemes with similar lightnesses. In this case, using dark blue (navy), dark red, and black together would not make the design visible for visually impaired or elderly people.

A color scheme is a selection and arrangement of colors in an organized manner. The selection of a certain color scheme over another one purely depends on the design intent and the design idea of a product or space.

Color Spreading, Neon Color Spreading, and Watercolor Illusion

Synonyms

[Color spreading](#); [Filling-in](#); [Visual illusions](#)

Definition

The color spreading is a long-range assimilative spread of color emanating from a thin-colored contour running in the same direction/continuation or being contiguous/adjacent to a darker chromatic contour and imparting a figure-ground effect across a large area. The two main examples of color spreading are the well-known neon color spreading and the watercolor illusion.

Neon Color Spreading

In 1971, Varin [1] studied a novel “chromatic spreading” phenomenon induced when four sets of concentric black circumferences, arranged in a cross-like shape, are partially composed of blue arcs, thus producing a virtual large central blue circle (Fig. 1a). The virtual circle appears as a ghostly transparent circular veil of chromatic translucent diffusion of bluish tint spreading among the boundaries of the blue arcs and filling in the entire illusory circle, induced by the terminations of the black arcs (Fig. 1).

This phenomenon was independently reported a few years later from Varin’s discovery by van Tuijl [2], who named it “neon-like color spreading.” He used a lattice of horizontal and vertical black lines, where segments of different colors (e.g., blue) create an inset diamond shape. The main outcome reveals again a tinted transparent diamond-like veil above the lattice (Fig. 1b).

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 1 Neon color spreading: The central virtual circle (a) and the inset virtual diamond shape (b)

Geometrically, the main geometrical property of all the known cases of neon color spreading is the continuation of one contour, usually black, in a second contour with a different color or, differently stated, a single continuous contour changing from one color to another. Phenomenally, color spreading manifests coloration and a figural effect described in detail in the following sections.

Coloration Effects in Neon Color Spreading

The phenomenology of the coloration effect within neon color spreading depends on the luminance contrast between the two inducing contours and is summed in the next points [2, 3]. (i) The color is perceived as a diffusion of a certain amount of pigment of the inset chromatic segments. (ii) The appearance of the coloration is diaphanous like a smoggy neon upon the background or (under achromatic conditions) like a shadowy, dirty, or filmy transparent veil. (iii) Under conditions where the inset figure is

appear as a ghostly overlapping transparent veil of bluish tint spreading among the boundaries of the blue components

achromatic and the surrounding inducing elements chromatic, the illusory veil of the inset figure appears tinted not in the achromatic color of the embedded elements, but in the complementary color of the surrounding elements, e.g., the achromatic components appear to spread greenish or bluish illusory colors, respectively, with red or yellow inducers.

Figural Effects in Neon Color Spreading

The apparent coloration of neon color spreading is related to its figural effects. Phenomenally, (i) the illusory neon coloration manifests a depth stratification appearing in front of the inducing elements; (ii) it is also perceived as a transparent film; (iii) by reversing the relative contrast of inset versus surrounding components, the depth stratification reverses accordingly (Fig. 2); (iv) the illusory colored region, under different chromatic conditions, may assume different figural roles by becoming, for example, a superimposed “light,” a “veil,” a “shadow,” or a “fog.”

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 2 By reversing the relative contrast of inset versus surrounding components (cf. Fig. 1), the depth stratification of neon color spreading reverses accordingly

Watercolor Illusion

The “watercolor illusion” is a long-range spread of color diffusing from a thin-colored contour adjacent to a darker chromatic contour and imparting a clear figural effect within large regions [4–9]. In Fig. 3, purple wiggly contours flanked by orange edges are perceived as undefined curved solid shapes, similar to peninsulas emerging from the bottom, evenly colored by a light veil of orange tint spreading from the orange edges.

By reversing purple and orange contours of Fig. 2, the coloration and figure-ground organization are reversed, and, thus, two orangish peninsulas, going from the top to the bottom, connected to the mainland at the top, are now perceived (Fig. 4). Briefly, what appears as illusory colored and segregated in one figure is perceived as empty space without a clear coloration in the other figure and vice versa. Therefore, the peninsulas of Figs. 3 and 4 pop up as totally different objects not referable to the same juxtaposed contours.

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 3 Two undulated peninsulas emerging from the bottom are perceived illusorily colored by a light veil of orange tint spreading from the orange edges

Coloration Effects in the Watercolor Illusion

The phenomenology of the coloration effect in the watercolor illusion reveals the following main attributes:

- (i) As in neon color spreading, the illusory color is approximately uniform. As shown in Fig. 5, the coloration, within the regions where the orange contours are closer, is the same as within the regions where they are distant.
- (ii) The coloration extends up to about 45.
- (iii) It is complete by 100 ms.
- (iv) Similarly to neon color spreading, all chromatic colors can generate the illusory coloration, as shown in Fig. 6, where an undefined irregular peninsula appears filled with a light blue tint. It should be noted that

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 4 By reversing the purple and orange contours of Fig. 3, the coloration and the figure-ground segregation is reversed: the two peninsulas going from the top to the bottom and connected to the mainland at the top

this peninsula is the Mediterranean Sea when the two adjacent chromatic contours are reversed. The watercolor illusion can also be induced with achromatic contours.

- (v) The coloration occurs on colored and black backgrounds. In Fig. 7, an undefined irregular peninsula (the Mediterranean Sea when the contours are reversed) appears filled with a purple tint.
- (vi) The optimal contour thickness is approx. 6 arcmin.
- (vii) The effect is stronger with wiggly contours, but it also occurs with straight contours and with chains of dots as shown in Fig. 8 [5, 6].
- (viii) High luminance contrast between inducing contours shows the strongest coloration effect; however, the color spreading is clearly visible at near equiluminance (see Fig. 9) [5, 6].

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 5 The apparent coloration is approximately uniform, i.e., the coloration, within the regions where the orange contours are closer, is the same as the regions where they are distant

- (ix) The contour with a lower luminance contrast relative to the background spreads proportionally more than the contour with a higher luminance contrast.
- (x) The color spreads in directions other than the contour orientation.
- (xi) By reversing the colors of the two adjacent contours, the coloration reverses accordingly.
- (xii) Phenomenally, the coloration appears solid, impenetrable, and epiphanous as a surface color.
- (xiii) Similarly to neon color spreading [1–3], the watercolor illusion induces a complementary color when one of the two juxtaposed contours is achromatic and the other chromatic (see Fig. 10) [5]. The inside of the zigzagged annulus appears yellowish.

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 6 All the colors can generate the coloration effect of the watercolor illusion: the undefined irregular peninsula appears filled with a light blue tint

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 7 The coloration occurs on colored and black backgrounds: an undefined irregular peninsula appears filled with a purple tint

Figural Effects in the Watercolor Illusion

The main properties of the figural effect are the following:

- (i) The watercolor illusion strongly enhances the “unilateral belongingness of the boundaries” [6, 7, 10].
- (ii) As in neon color spreading, the figural effect of the watercolor illusion is clearly perceived although it occurs in a different mode of appearance. The figure shows strong depth

segregation and a volumetric rounded and three-dimensional attribute, while the perceived variation of color, going from the boundaries to the center of the object, is seen as a gradient of shading, as if light were reflected onto a volumetric and rounded object. Figure 11 shows undefined, rounded, and volumetric shapes differing from one row to another on a shapeless empty space due to the unilateral belongingness of the boundaries. The stars are totally invisible.

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 8 The watercolor illusion is stronger with wiggly contours, but it also occurs with chains of dots

- (iii) By reversing the colors of the two adjacent contours, the figure-ground segregation reverses accordingly. In Fig. 12, the same elements of Fig. 11, illustrated with reversed purple-orange contours, appear like juxtaposed stars. The undefined shapes differing from one row to another are now invisible.
- (iv) Under the previous conditions, the figure-ground segregation is not reversible and unequivocal.
- (v) The watercolor illusion determines grouping and figure-ground segregation more strongly than the Gestalt principles of proximity, good continuation, *Prägnanz*, relative orientation, closure, symmetry, convexity, past experience, similarity, surroundedness, and parallelism [6, 7, 10]. In Fig. 13, some examples showing the watercolor illusion respectively against and in favor of surroundedness, relative orientation, good continuation, past experience, and parallelism are illustrated.
- (vi) By reversing the luminance contrast of the background, e.g., from white to black, while the luminance contrast of the contours is kept constant, the figure-ground segregation reverses (Fig. 14) [10]. Going from the bottom to the top of the figure, the crosses become stars. These results are in contrast to Gestalt claim that the currently figural region is maintained even on black/white reversal.

This suggests that the watercolor illusion includes a new principle of figure-ground segregation, the asymmetric luminance contrast principle, stating that, all else being equal, given an asymmetric luminance contrast on both sides of a boundary, the region whose luminance gradient is less abrupt is perceived as a figure relative to the complementary more abrupt region, which is perceived as a background [10].

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 9 High luminance contrast between inducing contours shows the strongest coloration effect;

however, the color spreading is clearly visible at near equiluminance

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 10 The inside of the zigzagged annulus appears yellowish

Similarities and Differences in Between the Two Illusions

By summing up the phenomenology of coloration and figural effects in both neon color spreading

and watercolor illusion, the former differs from the latter in both the appearance of the coloration (respectively, transparent vs. solid and impenetrable and diaphanous vs. epiphanous) and in the figural effects (respectively, transparent vs.

Color Spreading, Neon Color Spreading, and Watercolor Illusion,

Fig. 11 Watercolored undefined shapes differing from one row to another

opaque and dense and appearance as a “light,” a “veil,” a “shadow,” or a “fog” vs. rounded, thick, and opaque surface bulging from the background).

In spite of these differences, the two illusions are phenomenally similar in their clear color spreading and depth segregation. It is suggested [5] that while the similarities may depend on the local nearby transition of colors, equivalent in both illusions, the differences may be attributed to the global geometrical boundary conditions, dissimilar in the two illusions. As a matter of fact, while the neon color spreading is elicited by the continuation in the same direction of two contours of different

colors, the watercolor illusion occurs through their juxtaposition.

If this is true, the phenomenal differences between the two illusions can be reduced or eliminated through geometrical variations that bring both phenomena to a common limiting case placed in between and based on the local nearby transitions of colors.

A Limiting Case

Figure 15 shows four conditions that gradually introduce the limiting case. Figure 15a illustrates a neon color spreading that represents the starting

Color Spreading, Neon Color Spreading, and Watercolor Illusion,

Fig. 12 The same elements of Fig. 11, illustrated with reversed purple-orange contours, appear like juxtaposed stars

condition where concentric purple arcs continue by becoming orange. Now, the resulting inset square annulus appears as a transparent veil of orange color not like a ghostly circular veil of translucent color as in Fig. 1. This difference in the color and figural appearance is likely related to the high contrast between the two inducing colors.

Gradual steps toward the final combination of the two illusions in a limiting case are illustrated in Fig. 15b, c. Geometrically, in Fig. 15b, the orange inset arcs are reduced to short dashes, creating a condition in between neon color spreading and the watercolor illusion: from the neon

color spreading perspective, the inducing elements are contours *continuing* in short dashes (or elongated dots), but from the watercolor perspective, the terminations of the inducing arcs contain *juxtaposed* short dashes. Under these conditions, a coloration effect, not weaker than that of Fig. 15a, is perceived. However, it manifests a poor diaphanous and surface appearance. The illusory figure appears as a fuzzy square annulus, yellowish and brighter than the back-ground. It is worthwhile to note that the further reduction of the dashes to dots does not change significantly the strength of these effects.

The geometrical reduction in between neon color spreading and the watercolor illusion and opposite to the one of Fig. 15b is illustrated in Fig. 15c. Under these further conditions, all else being equal, short dashes become the purple arcs

of Fig. 15a. Now the coloration effect is weaker than that of Fig. 15a.

Given these geometrical prerequisites, the final step toward the limiting case becomes immediate and consists in putting together the previous

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 13 Some examples showing the watercolor illusion respectively against and in favor of

surroundedness, relative orientation, good continuation, past experience, and parallelism

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 13 (continued)

opposite reductions as shown in Fig. 15d. The results show that by reducing both the purple and orange arcs of Fig. 15a to short dashes, the coloration and figural effects do not change significantly [5]. This is corroborated by previous outcomes according to which the watercolor illusion occurs not only by using juxtaposed lines but also by using juxtaposed chains of dots [6, 7, 10]. Under these conditions both coloration and figural effects

become weaker and weaker as the density of the dots becomes sparser and sparser.

The two-dot juxtaposition of Fig. 15d can be considered as a true limiting case for neon color spreading and the watercolor illusion. As a matter of fact, (i) the two-dot limiting case can be considered as the geometrical common condition, beneath. (ii) The strength of both coloration and figural effects does not change

Color Spreading, Neon Color Spreading, and Watercolor Illusion,

Fig. 14 By reversing the luminance contrast of the background, from white to black, while the luminance contrast of the contours is kept constant, the figure-ground segregation reverses: going from the bottom to the top of the figure, the crosses become stars

significantly; therefore, the specific mode of appearance of coloration and figural effects in the two illusions is elicited by different local and global distributions of nearby transitions of colors that, in their turn, induce different boundary organizations. (iii) Phenomenally, the differences between the two illusions, where the inner changes are based on continuation and juxtaposition of contours, can now be reconsidered and unified in terms of transition. This is not only a linguistic alternative but also it can bring advantages by providing support for a simple common neural model. (iv) The limiting case can suggest variations of the two illusions that manifest coloration and figural attributes in between the neon color spreading

and the watercolor illusion, as shown in the next section.

Near the Limiting Case

By increasing the width of one of the two juxtaposed contours of the watercolor illusion to such an extent that the contour becomes a surface, the watercolor illusion manifests geometrical properties similar to the neon color spreading and, as a consequence, also shows different coloration and figural effects. The resulting coloration does not assume surface color properties, but properties more similar to the neon color spreading. It appears diaphanous like a foggy coloration

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 15 (a) The neon color spreading defined by the continuation of lines of different color; (b) a condition in between neon color spreading and

watercolor illusion, where the orange inset arcs are reduced to short dashes; (c) a condition in between the two illusions, where the purple surrounding arcs of (a) are reduced to short dashes; (d) the two-dots limiting case

diffusing everywhere in the background or as a colored light (Fig. 16).

Similarly to the previous condition, the coloration effect of Fig. 17 gives to the illusory star a fuzzy luminous quality. While in Fig. 16 the coloration belongs to the background, in Fig. 17 it belongs to the figure; however, the star does not manifest a strong surface appearance, but its inner surface appears brighter and yellowish and foggy and smooth.

Taken together, these figures suggest that (i) the modes of appearance of coloration are strongly related to boundary conditions that induce specific figural effects; (ii) by changing the boundary conditions, coloration and figural

attributes are perceived more similar to one, to the other illusion, or in between; and (iii) given this variety of appearances on the basis of different conditions, a simpler set of boundary cases, like in the limiting case, can unify both effects using local transitions of colors and can help to explain similarities and dissimilarities of the two illusions.

Neural Mechanisms Underlying the Two Illusions

On the basis of the previous results, coloration and figural effects may derive from parallel processes.

Color Spreading, Neon Color Spreading, and Watercolor Illusion,

Fig. 16 A light blue coloration filling in the inset square appears surrounded by a red spreading. The coloration effect is not accompanied by a figural effect with a plain volumetric property, but it appears diaphanous like a foggy veil of color

Color Spreading, Neon Color Spreading, and Watercolor Illusion, Fig. 17 The illusory coloration of the star appears fuzzy and luminous, and it manifests a poor surface appearance

At a feature processing stage, the short-range interaction area around and in between the two dots produces the color spreading common to both illusions, and at a parallel boundary processing stage, the different geometrical structures in both illusions organize the color spreading to elicit different figural effects. Moreover, the

reduction of the neon color spreading and watercolor illusion to a common limiting case can suggest a common and an easier explanation that can be based on the FACADE neural model of biological vision [5]. The model posits that two processes, boundary grouping and surface filling-in [11, 12] substantiated by the cortical interblob and blob streams, respectively, within cortical areas V1 through V4, are responsible of how local properties of color transitions activate spatial competition among nearby perceptual boundaries, with boundaries of lower-contrast edges weakened by competition more than boundaries of higher-contrast edges. This asymmetry induces spreading of more color across these boundaries than conversely. These boundary and surface processes show complementary properties that can also predict how depth and figure-ground effects are generated in these illusions.

Other related findings to both illusions [13–15] showed that neurons in V2 respond with different strength to the same contrast border, depending on the side of the figure to which the border belongs, implying a neural correlate process related to the unilateral belongingness of the boundaries. Figure-ground segregation may be processed in areas V1 and V2, in inferotemporal cortex and the

human lateral occipital complex. Also the color spreading of the two illusions might have its explanation in the cortical representation of borders [9].

Summary

The color spreading is a long-range assimilative spread of color emanating from a thin-colored contour running in the same direction/continuation or being contiguous/adjacent to a darker chromatic contour and imparting a figure-ground effect across a large area. Two main examples of color spreading are the well-known neon color spreading and the watercolor illusion. The coloration and the figural properties of the two illusions, studied using phenomenal and psychophysical observations, can be reduced to a common limiting condition, i.e., a nearby color transition called the “two-dots limiting case,” which explains their perceptual similarities and dissimilarities and suggests a common explanation.

Color synaesthesia

Definition

Color synesthesia is a condition in which sensory or cognitive inducers elicit involuntary, atypical, concurrent color experiences.

Marks of Color Synesthesia

Synesthesia is a condition that involves unusual pairings across modalities. In color synesthesia, a sensory or cognitive stimulus such as a grapheme or a sound automatically and involuntarily induces specific color experiences. Various types of color synesthesia have been identified,

including calendar-color synesthesia, sound-color synesthesia, taste-color synesthesia, and even fear-color synesthesia. However, the most prevalent form of the condition is grapheme-color synesthesia, where numbers or letters induce highly specific color experiences [1].

One of the marks of grapheme-color synesthesia is that it exhibits test-retest reliability, meaning that the synesthetic colors subjects identify relative to specific stimuli in the initial testing phase are nearly identical to those identified in retesting phases [1] (see Fig. 1).

Another mark of grapheme-color synesthesia is its uniqueness: synesthetic inducer-concurrent pairs are unique for each individual [1, 2]. For example, the letter A may induce a synesthetic experience of redness in one grapheme-color synesthete but a synesthetic experience of blueness in another. In fact, each grapheme has been found to trigger each of the 11 Berlin and Kay colors in different grapheme-color synesthetes (i.e., red, pink, orange, yellow, green, blue, purple, brown, black, white, gray). Another aspect of the uniqueness of the grapheme-color synesthesia is how the synesthetic colors are experienced [3]. Projector grapheme-color synesthetes see synesthetic colors as projected out onto the world. Pop-up effects are taken to be signifiers of projector synesthesia. Associator grapheme-color synesthetes, by contrast, experience colors in the mind's eye. Their synesthetic colors are triggered by automatic retrieval of mnemonic associations, which are more akin to mental imagery than to remembering something learned in childhood [4]. Both projector and associator grapheme-color synesthesias involve the triggering of a highly specific and automatic inducer such as a colored letter or number.

Notwithstanding the individual differences among grapheme-color synesthetes, studies indicate that synesthetes show significant group preferences for certain grapheme-color associations [5]. For example, grapheme-color synesthetes tend to associate the letter *a* with red, the letters *i* and *o* with black or white, and the letter *n* with brown. These associations are not entirely random. While studies suggest that the experiences between grapheme-color synesthetes and non-

Color Synesthesia, Fig. 2 When normal subjects are presented with the figure on the *left*, it takes them several seconds to identify the hidden shape. Some grapheme-color synesthetes instantly see the *triangular* shape because they experience the 2s and the 5s as having different colors

synesthetes differ significantly, there are some common grapheme-color preferences among the two groups [6]. For example, both grapheme-color synesthetes and (forced- or free-choice) controls associate the letter *f* with green, the letter *b* with blue, and the letter *v* with purple.

High-Level Versus Low-Level Synesthesias

An open question about grapheme-color synesthesia is whether it is triggered by low-level perceptual features (such as the curvature of the number 3) or high-level perceptual features of inducers (such as concepts inherent in a grapheme). Collectively, the evidence seems to indicate that both low- and high-level synesthesias occur in different individuals [4].

Some grapheme-color synesthetes seem to experience a pop-out effect in visual search experiments. For example, if a cluster of 2s is embedded

in an array of randomly placed 5s, normal subjects take several seconds to find the shape formed by the 2s, whereas for some grapheme-color synesthetes, 5s pop-out instantly (see Fig. 2) [7].

Pop-out effects seem to indicate that some grapheme-color synesthesias are triggered by low-level perceptual features because they involve segregation. Specifically, grapheme-color synesthetes are able to experience the targets and the distractors as distinct stimuli: the 5s (which function as the target) are seen as forming a triangle and appear to be distinct from the 2s (which function as the distractors). Since only perceptual features processed early in visual processing can lead to segregation, pop-up effects seem to provide support for low-level grapheme-color synesthesias [7]. Pop-out effects are also taken to be evidence for projector grapheme-color synesthesias. Projector grapheme-color synesthetes see synesthetic colors as projected out onto the world. The induced colors (in Fig. 2) are experienced as belonging to the 2s and 5s

seen on the template; they are not experienced as mere associations.

Visual search experiments that give rise to pop-out effects raise the question of whether synesthesia requires focused attention. If an inducer elicits synesthetic colors without it being attended, then a target (e.g., a 5 in Fig. 2) that has a distinct synesthetic color from a distractor (e.g., a 2 in Fig. 2) should capture attention and lead to highly efficient identification. But if an inducer does not elicit synesthetic colors until it is attended, then the identification would be relatively inefficient.

Although some findings appear to suggest that pop-out effects occur preattentively, upon closer investigation, the current evidence indicates that an inducer does not elicit synesthetic colors until it is attended. One study [8] used a variation on the standard visual search experiment to test a subject's (J) search efficiency. J was shown an array of black graphemes on a colored background, some of which induced synesthetic colors. The colored background was either congruent or incongruent with the synesthetic color of the target. The researchers found that J was more efficient in her search when the background and the synesthetic color were incongruent than when they were congruent. This indicates that synesthetic colors attracted attention only when they were clearly distinct from the background. In another study, a subject, PM, was able to identify graphemes quickly but only when the target was within a few degrees of visual angle from fixation, indicating that PM's synesthesia is within the focus of attention [9].

Other findings seem to nevertheless indicate the presence of low-level synesthesia. For example, one study found that the strength of the induced colors in one grapheme-color synesthete (JC) varied depending on whether the graphemes were presented in high or low contrast [10]. JC's synesthetic colors were reduced or absent at low contrasts but not at high contrasts. Since JC's synesthesia is elicited by low-level features (i.e., high contrast), this study indicates the presence of low-level synesthesia.

All of the aforementioned studies indicate the presence of low-level synesthesia. However, studies also seem to provide support for high-level

synesthesias. In one experiment, a single grapheme induced different synesthetic colors depending on the context, e.g., the category or concept associated with the inducer. In one subject, the middle letter "H" induced a red synesthetic experience when she read the word shown in Fig. 3 as "CAT" but a brown synesthetic experience when she reads the word as "THE" [7].

In a similar experiment, color-grapheme synesthetes (JC and ER) were able to switch between their synesthetic colors when they were shown Navon-type figures such as an image of a large 5 constructed using smaller 3s (Fig. 4) [11]. For example, attending to the entire figure (i.e., the number 5) induced one synesthetic color, but attending to its parts (i.e., the smaller 3s comprising the 5) induced another. Similarly, when a display that could be viewed either as the letters I and V placed next to each other or as the Roman numeral four, synesthetic colors were induced only in the former case [7]. The fact that the very same grapheme can induce different synesthetic colors depending on the context in which it occurs suggests that some grapheme-color synesthesias are triggered by high-level perceptual features. It is possible that such contextual effects associated with high-level synesthesia are the result of top-

Color Synesthesia, Fig. 3 Synesthetes interpret the middle letter as an A when it occurs in "CAT" and as an H when it occurs in "THE." The color of their synesthetic experience will depend on whether the grapheme is considered part of the word "CAT" or "THE"

Color Synesthesia, Fig. 4 Some synesthetes are able to switch between their synesthetic colors when they were shown Navon-type figures such as an image of a large 5 constructed using smaller 3s. Two different synesthetic colors are induced depending on whether synesthetes attend to the entire figure, the number 5, or it's parts, the 3s that comprise the 5

down modulation on early visual processing [7]. If so, these cases may turn out to be cases of low-level synesthesia.

Cognitive and Neural Mechanisms

The precise cognitive and neural mechanisms underlying color synesthesia are unknown. Some propose cognitive models of synesthesia based on the modularity thesis about processing. The modular theory holds that functionally individuated and introspectively opaque, encapsulated subunits of the mind process information in a way akin to a computer. One hypothesis is that synesthesia occurs when there is a breakdown in encapsulation between modules that process color and whatever other sensory or semantic features are involved [5, 12]. Others contend that synesthesia might result from the presence of an extra-module whose function is the mapping from a sensory or semantic input to a cross modal output [13].

A second type of account appeals more directly to the neural mechanisms underlying synesthesia. Structural connectivity mechanisms have been

proposed for standard cases of grapheme-color synesthesia and sound-color synesthesia, suggesting unusual connectivity between color areas in the visual cortex and the adjacent visual word form area or the auditory cortex [7, 10]. Evidence for this hypothesis comes from brain-imaging studies showing enhanced anatomical connectivity near the implicated brain regions in grapheme-color synesthesia [14] and sound-color synesthesia [15].

Functional connectivity mechanisms have also been proposed for color synesthesia, according to which neural networks that give rise to synesthetic experiences exhibit excessive disinhibition or hyperexcitement of neurotypical connections through a change in neurotransmitters [16]. On one version of this hypothesis, color synesthesia is due to disinhibited feedback from an area of the brain that binds information from different sensory modalities [17]. Evidence for this hypothesis comes from an analogous case in which a patient PH reported seeing visual movement in response to tactile stimuli following acquired blindness [18]. As PH was blind, he could not have received the information via standard visual pathways. It is plausible that PM's synesthetic experience results from disinhibited feedback from brain regions that receive information from other senses.

The fact that synesthetic experiences can arise when subjects are under the influence of psychedelics provides further evidence for functional connectivity mechanisms [19, 20]. It has been shown in several studies that psychedelic hallucinogens that function primarily as serotonin agonists, such as psilocybin, LSD, and mescaline, often induce transient synesthesia, presumably through an alteration of functional brain connectivity [19, 21]. It is unknown, however, whether drug-induced synesthesia and developmental synesthesia have the same underlying mechanism.

On another version of the hypothesis that synesthesia is due to aberrant functional connectivity, color synesthesia arises as a result of aberrant reentrant processing [22]. This proposal is akin to the disinhibited feedback hypothesis but suggests specifically that high-level information reenters color areas in the visual cortex and that it is this form of reentrant information processing that

leads to the experience of synesthetic colors. This model would explain why visual context and meaning typically influence which synesthetic colors a grapheme gives rise to [2].

Yet another hypothesis is that some forms of color synesthesia are learned in early childhood, for example, as a result of repeated exposure to refrigerator magnets [4]. Grapheme-color binding, for example, may in some cases be the result of enhanced activation of color areas in the visual cortex in response to automatically triggered semantic memory recall [23–25]. Whether color synesthesia can be acquired in adulthood through similar perceptual learning mechanisms remains to be seen.

It is plausible that different forms of color synesthesia proceed via different mechanisms. Cases of color synesthesia have been reported in which the visual cortex is not involved in generating synesthetic colors [26]. None of the aforementioned hypotheses, despite their plausibility in run-of-the mill cases, can explain more unusual cases of color synesthesia.

Cognitive Advantages of Color Synesthesia

Various cognitive advantages have been claimed for synesthesia. Some case studies suggest that

grapheme-color synesthetes may have greater recall ability for digits and written names when compared to non-synesthetes [27].

In rare cases, color synesthesia has been associated with extreme mathematical skills. Subject DT, for example, sees numbers as three-dimensional colored, textured forms [28]. His synesthesia gives him the ability to multiply high numbers very rapidly. He reports that the product of multiplying two numbers is the number that corresponds to the shape that fits between the shapes corresponding to the multiplied numbers. Subject DT's color synesthesia also gives rise to extreme mnemonic skills. DT currently holds the European record in reciting the decimal points of the number pi (π). An fMRI study comparing DT to controls while attempting to locate patterns in number sequences indicated that DT's synesthetic color experiences occur as a result of information processing in nonvisual brain regions, including temporal, parietal, and frontal areas [28]. This advantage may be facilitated by top-down modulation and has been used to support the view that photisms represent letterocity or numerocity [29].

Another subject, JP, was found to have exceptional abilities to draw complex geometrical images by hand and a form of acquired synesthesia for mathematical formulas and moving objects, which he perceives as colored, complex geometrical figures [26] (see Fig. 5).

Color Synesthesia,
Fig. 5 Image hand-drawn
by subject JP

Color Synesthesia, Fig. 6 Sagittal slices. Activation induced by the image-inducing formula contrasted to non-inducing formulas. The SPM(T) maps were

thresholded at family-wise-error-corrected p -value 0.01 and overlaid on JP's structural T1-weighted MRI which was standardized into MNI-space using SPM8 [26]

JP's synesthesia began in the wake of a brutal assault that led to unspecified brain injury. A fMRI study contrasting activity resulting from exposure to image-inducing formulas and non-inducing formulas indicated that JP's colored synesthetic images arise as a result of activation in areas in the temporal, parietal, and frontal cortices in the left hemisphere. The image-inducing formulas as contrasted with the non-inducing formulas induced no activation in the visual cortex or the right hemisphere [26] (see Figs. 5 and 6).

This case also suggests that at least some forms of color synesthesia can give rise to cognitive advantages in the area of mathematics. As the visual cortex does not appear to be directly involved in generating the synesthetic images, it also suggests that at least some forms of the condition are best characterized as forms of top-down modulation that proceeds via nonstandard mechanisms.

Enhanced creativity may be another advantage conferred by synesthesia. There is some evidence that synesthetes are on average more likely to work as artists [30, 31]. Both synesthesia and creativity involve linking unrelated ideas to reveal deep similarities, which may be due to the greater connectivity between processing areas [7].

Color Transfer

Erik Reinhard
InterDigital, Cesson-Sévigné, France

[Color mapping](#)

Definition

Color transfer is the name given to a set of technologies that aim to alter the colors in an image or video by means of an example image or video. Thus, the mood or color scheme of an image can be changed to resemble that of another image, without the need to paint over pixels or manually alter an image's color palette.

Key Principles

Editing colors with traditional tools can be a laborious and time-consuming task. Professional color grading tools are complex and often expensive pieces of software that take time and effort to master. Rather than use buttons and sliders to adjust the color properties of an image, a convenient alternative may be to find an example image (also known as reference image) which already has the desired color mood. Using the colors

defined in the example image, color transfer methods try to alter the colors of the input image to match those of the example image.

The choice of example image is often determined by its use case. In a creative context the example image can be anything the user may imagine. When stitching panoramas, the individual shots may be matched to each other. In professional color grading, shot-to-shot matching may benefit from color transfer technologies help to unify the color schemes between shots. Here, the example image(s) will come from one of the shots.

Dependent on use case, different methods may be applicable. In the most general case, the input and example images are unrelated. In such case, statistical methods may be employed to transfer certain color characteristics from the example image to the input image.

If, on the other hand, it is known that the input and example images depict the same scene, then correspondences between the two images can be calculated, so that pixels depicting the same objects are known. This information can then be used to determine the mapping of colors between the two images in a meaningful and spatially varying manner.

The idea behind color transfer is that the user only needs to select an appropriate example image to apply its colors to an input image. This offers convenience, even if sometimes it may be difficult to predict the outcome. For this reason, non-automatic color transfer methods were developed that offer the user a high level of control over the result, without the need to resort to knobs and sliders to set the desired appearance.

The recent trend in computing to solve all manner of problems using deep neural networks has also given rise to network-based color transfer solutions.

Finally, color transfer is normally aimed to transfer the mood or appearance of an image to another image. However, the definition of mood or appearance is rather vague, and as a consequence there is typically no ground truth available. This makes it difficult to know when a particular transfer of color has been successful.

Each of these topics is discussed in the following sections.

Statistical Methods

Because human vision has three cones types which mediate color vision, color spaces can be three dimensional. Often this means that a color is specified as a mixture of red, green, and blue (R, G, and B). However, for natural images, RGB color spaces are highly correlated: the value of the red color channel tends to be a good predictor of the corresponding values of the green and blue channels. This is so because for natural scenes the average reflectance of its objects tends to gray. In an RGB color space this is represented as equal levels for the red, green, and blue channels. While correlations between channels can be used to create color constancy algorithms (see Color Constancy: https://doi.org/10.1007/978-3-642-27851-8_266-1), this is not good for easy manipulation of images.

One of the oldest color transfer algorithms [1] is based on a simple insight related to color spaces: if correlations between color channels can be minimized, then color transfer could be simplified to straightforward operations affecting each of the three color channels independently. For natural images, a well-chosen color opponent space can do just that: formally color opponent spaces can decorrelate the color channels. In practice, the channels become near independent [2].

Thus, by transforming both input and example images to such a color opponent space, the color channels can be processed independently. The simplest transfer of color properties then consists

of shifting and scaling the pixels in each channel independently so that the input image will have the same overall means and standard deviations as the example image [1]. Then, the input image is transformed back to a suitable RGB color space. An example result obtained with this technique is shown in Fig. 1.

The assumptions of the above algorithm on the color statistics of the two input images are rather strong. It is assumed that the conversion to a color opponent space leads to 1D distributions that are independent from each other. They should each be unimodal. While this may be true approximately for some images, this would not be true in the general case. Especially if the target image has a single dominant color, for example mostly greens or reds, or the desired color palette is achromatic, then the transfer using the above method tends to produce reasonable results. This is largely the case for the example shown in Fig. 1. When the 3D distributions of the input and/or target images are more complex, the above method cannot match the target distribution, and other solutions would have to be sought.

Thus, such a simple algorithm can produce plausible results for a variety of input pairs, but equally there are many cases for which this approach fails. This has given rise to a great number of refinements, which each have contributed to either more robust or more plausible results.

For example, rather than relying on a single color space for all images, each input may be individually decorrelated [3], which can be achieved by applying Principal Components Analysis (PCA). However, a study on the choice

C

Color Transfer, Fig. 1 The two images on the left serve as input to a color transfer algorithm [1], to produce the result shown on the right

of color space has found that CIELAB using illuminant E provides the most plausible results, even out-performing PCA-based ensemble color spaces [2].

Alternatively, instead of simply transferring the means and standard deviations in each channel, a more sophisticated transfer may be achieved. For example, a partial and controllable histogram equalization could be applied in each channel independently [4]. It may also be constrained to avoid too large gradients in the output histograms [5].

Further, while using a decorrelated color space offers computational convenience, there are often corner cases which do not lead to plausible results. While on average per-channel methods may perform reasonably well, there will be many image pairs for which this is not the case. To increase the robustness of color transfer, it may therefore be advisable to consider applying a single transfer in 3D color space, instead of three one-dimensional and independent transfers [6]. This process may lead to some extraneous graininess, which can be removed using an appropriate post-process [7]. Examples of this method are shown in Fig. 2.

An interesting observation is that a good color transfer algorithm not only transfers the color palette from one image to another, but it also minimizes the amount by which each pixel is transformed. This can be achieved by formulating the problem as Monge's optimal transportation problem [8]. A linear optimal transport transfer is shown in Fig. 3. Non-convex relaxation may be applied as well [9, 10], as shown in the same figure.

Additional fidelity may be obtained by applying color transfer to image regions, rather than globally in one go to the entire image. To this end, the input and example images may be segmented or clustered, for example using expectation maximization to fit a Gaussian mixture model [11] or the mean shift algorithm. There are many other ways in which image regions can be clustered or the color transfer can be restricted or guided. This includes style-aware clustering, texture-based clustering, saliency-based color transfer as well as vectorization-based processing. Instead of transferring all colors of an example image to all pixels of an input image, a single

Color Transfer, Fig. 2 The two images at the top serve as input to an N-dimensional color transfer algorithm [6] (bottom left). Its output is subsequently passed through a regaining method [7] to produce the final image (bottom right)

Color Transfer, Fig. 3 The two images at the top of Fig. 2 serve as input to a color transfer algorithm based on Monge's optimal transportation problem [8] (left). The image on the right shows a result obtained using a different

Optimal Transport formulation [9, 10]. To enable a visual comparison, the bottom image shows Reinhard's method of color transfer [1]

object in an input image may be the target for color transfer.

Color space itself can also be clustered, for instance according to color naming conventions. This has the advantage that the transfer can be limited so that patches of a given name (e.g., "blue") stay within their color category.

Further fidelity can be obtained by also determining the material of objects in a scene. This knowledge could guide the transfer of colors, as demonstrated for portrait images, whereby image regions were classified as either skin, hair, or background [12].

After clustering, several techniques are available to perform the assignment of colors, including optimal transport theory [12].

Correspondence-Based Techniques

For applications whereby color adjustment is required to bring two or more images of the same scene in colorimetric alignment, the knowledge that the same scene is depicted may be exploited to either arrive at a simpler algorithm and/or at algorithms that operate with higher

fidelity. An example of a use case is panorama stitching, whereby multiple images of the same viewpoint are taken, which pairwise overlap. Here, color transfer may be used to ensure a consistent look between the images prior to stitching them together.

To aid the color transfer process, in such cases correspondences between the images may be computed first through feature detection and matching [13]. Points that correspond between two images can then be transferred, after designating one of the overlapping images as the input image and the other as the example image. Robustness of the transfer can be improved by considering neighborhoods around each feature point to derive the transfer function [14], for instance by using blur kernels or windowing.

Robustness could also be enhanced by explicitly using region-based feature matching techniques. Such an approach would typically involve either segmentation or a quad-tree decomposition.

In the case that one image of a pair needs to be corrected against another and the differences between them are rather large, the feature matching

algorithm should be chosen such as to produce a dense correspondence [15].

Non-Automatic Methods

While the paradigm to control an image's colors by example is attractive in many situations, there are times when more control over the final result may be required. In such a case, it may be possible to guide the transfer by a combination of an example image and additional user input.

Such user input may consist of strokes, whereby the user paints certain image areas. This can be used either to manually determine correspondences, or to prevent certain regions to participate in the transfer. Further, the user defined scribbles themselves may serve as initialization or reference to guide the color transfer. User input may also involve the selection of pairs of image regions, or swatches. These can be used to manually steer the color transfer.

Machine Learning Techniques

Machine learning techniques, and especially deep learning techniques, have enabled style transfer, whereby not only the colors are transferred between images, but the entire style is transferred [16]. This often involves example images of a painterly style, so that a photographic input image attains a non-photorealistic style. The transfer itself can be achieved using convolutional neural networks (CNNs) [16]. By introducing appropriate regularization and semantic segmentation to a CNN, style transfer can attain a photorealistic look, thereby becoming effectively a highly powerful color transfer technique [17].

Measuring Success

With much work devoted to improving the quality of color transfer, a question that has arisen is that of how to evaluate the quality of the results. In the absence of ground truth it is difficult to know when one algorithm produces a better result than another. Even defining "better" in this context is difficult, because it depends strongly on human perception, and even on personal taste. Measuring

the success of a color transfer algorithm is therefore a difficult problem.

However, some approaches may help with the assessment of color transfer methods. For instance, a robust color transfer algorithm would produce plausible results when input and example images are swapped. This can be tested in a meaningful manner by assessing the quality of a round-trip conversion. Here a color transfer algorithm takes an input and an example image to produce a result image. If then the same algorithm is used to transform the result image according to the input image, then in theory the final output should resemble the original input image [18]. After this round-trip conversion, a standard color difference metric such as CIE94 (https://doi.org/10.1007/978-3-642-27851-8_13-1) or CIEDE2000 (https://doi.org/10.1007/978-3-642-27851-8_7-1) could be applied to assess the per-pixel error, where a smaller error points toward a more robust algorithm.

Alternatively, a metric based on user data has been constructed [19]. Here, the color transfer quality was assessed in a psychophysical experiment. Using input, example and result images, a set of features are then computed on the same data, after which a regression method was applied to the combined features and user data. This allows the method to predict the quality of color transfer on unseen input/example/result triplets.

Definition

Color trends are expected forthcoming market interest in some specific color shades.

Sociological Function of Color Trends

Color trends are temporal collective color preferences. They restrain individual- as well as group-specific color preferences and determine people's tastes and judgments over a certain period. Their application is typically not restricted to particular objects, contexts, or aesthetic conventions and is unconstrained by any functional, symbolic, or formal influences. Therefore, even colors with inherently negative symbolic meanings or connotations can become collectively preferred for a certain period. Individuals as well as society more generally perceive color trends as an articulation of "the predominant taste orientation." Anyone who adopts the trend demonstrates that she/he is open-minded, modern, and a member of an ideal (ized) peer group representing the *Zeitgeist*. In the end, using color trends also relieves individuals of mental strain. Those who adopt them avoid stylistic confrontation

and guarantee that their choices meet approval [1].

Cyclic Recurrence of Color Trends

Several studies [2–4], which analyzed the rise and fall of collective color preferences in architecture, interior design, and consumer goods during several decades, suggest a cyclic recurrence of color trends. Oberascher [5] points out that color trends must repeat in the long run because the potential gamut for color innovation is limited by the natural boundaries of the perceptual color space. New colors in a strict sense cannot be invented. Technological progress, however, may produce new color appearances. Based on an analysis of predominant color trends in furnishing and interior design in Germany and Austria between 1972 and 1992, he suggests a general model of the cyclic recurrence of collective color preferences. One explanation why certain color groups and ► **color combinations** are more likely to be repeated than others might be that the aesthetical evaluation and appreciation of color groups and combinations in general are determined by universal laws of perception and Gestalt psychology. But other factors may play a role. The emergence and spread of new collective color preferences are most probably rooted in a basic human desire (evolutionary, biological, neurophysiological, psychological, sociological) for change, alteration, renewal, and innovation. People's readiness to engage in new and unfamiliar colors increase over time as they become satiated with one trend. Since no new colors can be invented but only selected from the existing perceptual color gamut, those color groups and combinations that have been out of use for the longest time will appear novel. For young people these colors are new; for the older generations, they are a (re) contextualization of their color memories. The model of the cyclic recurrence of collective color preferences does not claim to predict color trends but might be used as a strategic tool for product marketing and management particularly in the furniture, furniture supply, and building material industry.

The Emergence of Color Trends

Historically, fashion has always set its rules and its trends based on a top-down pyramid approach. Every civilized society in its history has been able to use a large number of dye materials to color fibers, textiles, and leather in multiple shades. Where dye materials for some specific colors were lacking, international trade made up for it since they were imported, becoming widespread [6]. It can thus be said that no major color area has been neglected in the evolution of the trends and fashion of upper classes, but some color ranges have prevailed over others from time to time based on aesthetical, symbolic, and social choices imposed by the ruling classes.

A swing in trends occurred as ready-to-wear (prêt-à-porter) clothes and design became more widespread, and consumption democratization developed. Some spontaneous bottom-up trends have emerged since the 1960s. These have affected fashion, resulting in a combined top-down and bottom-up approach that is still underway, and it currently seems that street fashion is predominant [7].

Instruments to identify and anticipate market requirements were needed in order to properly respond to the new industrial organization of textile, clothing, furnishings, and design industries.

This has led to color trend forecast agencies, where teams of researchers (consisting of stylists, designers, sociologists, psychologists, and market experts) started to analyze consumption and behaviors and to anticipate color trends, ahead of the industrial manufacturing schedule required (2 years).

Not Only Colors, But Also Range Quality

Since then, color trends have renewed their offer season after season, not by changing major color families (red, yellow, green, etc.) but by the “quality of their range” (soft, bright, pastel, dusty, clear, dark, etc.). In the 1990s, surface finishing too became an element inherent to color as it changed its look, value, and “style.”

Historically, color trends have encapsulated the “spirit” of the time for many years. Their likelihood of meeting consumption demand results from the fact that they are based on the identification of color trends that are already found in the market, that the industry has adopted, and that the consumer has found within a predefined and limited available range, thus confirming relevant forecasts [8].

What Are Trends?

Trends are the expression of fashion themes and an indication of consumption and behavioral styles. They play two roles: on the one hand they are a monitoring tool for fashion and its multiple manifestations, and on the other hand, they anticipate and express current social orientations.

The life span of one or more trends on the market is very uncertain, from one season to several years.

The emergence of trends depends on historical, social, political, and cultural factors, which develop in the general public regularly and cyclically and influence almost a whole decade.

However, some very successful trends can come forth in a strange and sudden manner, as a result of occasional factors that have become very popular at a national or international level (a film, an exhibition, a music phenomenon, a product launch, the opening of new shops, some successful places open to the public, etc.).

Individualization of Color Trends

Today’s global market, where goods move freely, is unstable and difficult to control because many style orientations coexist simultaneously. Comparative analyses of major color trends often highlight dissimilarities in results, which are due to both the target and the impossibility to develop truly accurate forecasts. That is why color trends no longer play the role of universal consumption indicators; instead, they now act as a particularized anticipation of and focus on the themes intended for a specific market sector.

Companies use color trends to choose corporate colors for communication purposes as they try to develop a visible business identity, based on colors allowing them to stand out from competitors and to take advantage of mainstream tendencies by means of season’s colors. Albeit part of the general aesthetic framework, these color trends mark corporate choices and enable consumers to invent their own style through individual combinations.

This is the result of the current historical moment, known as “post-fashion,” where there are unclear and often contradictory signs and a fragmented coexistence of all types of different opportunities and orientations.

Creation of Color Trends

Color trends result from a research on ongoing social, cultural, and consumption changes, combining the quality and quantity data collected in order to develop an expected scenario.

The colors suggested by color trends have to play an intense and immediate communication role and must represent first a lifestyle than a consumption style one can identify oneself with. They must belong to the present time, be the continuation of the past, and prove to be able to anticipate the future.

As a matter of fact, the pursuit of novelties and changes cannot deviate much from tradition, from what consumers have shown to appreciate. Consequently, every color trend will contain some reassuring references in line with the latest successes and some innovations embodying the change.

Work Phases

Pompas points out the following work phases [9]:

- Registration of the latest most successful color trends
- Monitoring and insight of ongoing changes, based on a development process approach

- Collection of quantity and quality data on ongoing changes and their translation into dominant concepts
- Development of a scenario consisting of several images
- Selection of emerging shades and secondary shades
- Organization of a color range or ► [palette](#) that is consistent with dominant concepts
- Suggested ► [color matching](#), consisting in ► [color combinations](#)

Why to Be Aware of Trends

In the many areas of application and activities that involve the use of color, for instance, in industrial and textile design and in fashion design, only the creators of products who have the right information at the right time can act with advantages in the business environment.

There are many factors that need to be considered when predicting future design and color trends. There is an evolution from one season to the next; there are also important social and economic forces at work. One of the most important factors is the current and future projection of the socioeconomic conditions of the target consumer. Having a clear perception of changes, increasingly accelerated, it is possible to react quickly to the most demanding challenges of today's world.

The need arises from the spread now possible, at all levels, with simultaneity in all parts of the world, of the most important events. Due to the globalization of the marketplace, these factors are not as segregated by region as in the past. Of course, there are still major cultural influences that affect the interpretation of these factors.

Every new color or design trend starts because of a new influence or change of value perceived by the social group affected by these influences.

There are many reasons for the change of values, one of the most important being a shift in the emotional process of seeing and experiencing these changes. Visual and emotional influences, changes in economic and social

circumstances, and perception of new life styles affect the way in which people act in front of design and color. In a global environment of snapshot communications and accelerated pace of social and cultural changes, trends are constantly evolving to reflect those changes. Several organizations and color trend advisory services dedicate themselves to analyze the factors that will influence consumers' emotions. Their members track, analyze, predict, and direct colors and design of the consumer world. These groups base their color and design forecast on trends in fine arts, global events, technological advancements, economical and political circumstances, cultural facts, etc. and on the impact that these combined factors may have on the consumer. The media, opinion makers, specialized fairs, and producers deal with the effects of disclosing these facts and act on the choice of designs and colors. Based on this conceptualization, a new product will come, and it will be suitable to the market. If the designers have accurately identified and understood the customer, they will respond correctly to its own market.

Lifestyle Proposal

In 1985, the style of the products began to take into account the lifestyles [10].

The Advanced Communication Center, in France, divided the French population into five socio-lifestyles which then grew in number, diversifying. This study took into account:

- The places of residence of consumers
- Their behavior and preferences for the indoor environment: materials, objects, furniture, colors, and patterns
- The places where they buy or do their shopping
- The type of information used, newspapers, magazines, television and among other parameters

These data would compose an extremely useful tool to manage the offer of products.

Trends and Revivals

Particularly in the beginning of the twenty-first century, the succession of rapid changes in short and accelerated periods became relevant, leading to the overlapping of different revivals. The change in the nature of the geopolitical and cultural relationship impacts on the representation of the world, in the evolution of the conception and circulation of signs representing a moment. It is therefore essential the conceptual updating of the cultural and aesthetic debate, without neglecting the political, economic, and anthropological impact. It is of great interest therefore to assess how the arts of the image are carriers of elements of exchange, while it is necessary to avoid the danger of uniformity.

To propose a revival involves knowing the reality and the facts that gave rise and its implications. Taking only the outward, without understanding their reasons, leads to superficiality, the mere repetition. Investigating the roots pushes to motivation that is spilling into creativity.

Each of the decade 1970s, 1980s, and 1990s showed its spirit in a complex and multifarious use of color as a clear expression of the social premises of the time in western countries [11]. These trends are reflected in the product catalogs of European and American textile mills and department stores from 1970 to 2013, as well as in the main trade fairs such as Heimtextil (international trade fair for home textiles and commercially used textiles in Frankfurt), Star and Macef (Milan), Paritex and Maison et Objet (Paris), and among others, from 1971 to 2013.

The early 1970s kept the euphoric creativity of the 1960s as regards style. In 1973, however, great structural changes were brought about by the deep crude oil crisis which hit the markets and the economic structures. A feeling of uncertainty and lack of stability got hold of society. In the field of design, all this resulted in going back to a well-known past in search of the security purported in the everlasting values, either by retrieving old documents or manipulating eclectically their iconography. The desire of running away from reality was shown by all sorts of romantic attitudes such as revivals and retro-proposals.

Design turned back to small-scale motifs, geometrical or flowery. The *fleurettes* were monotonously added to all surfaces, and liberty style succeeded in west European countries. The predominant colors accompanying this stylistic shock ranged from medium to dark, grayish colors, non-saturated colors, earthy colors, grayish browns and greens.

The 1980s was the decade of appearance. The utmost egocentricity together with hedonism and obsession for social status was the more significant features in the group engaged in a blind and swift consumerism. It was the yuppie's decade, the decade of the self. The expanding social class was then the new bourgeoisie of the managerial elite, fond of showing off their success and their higher social position. The new style was sophisticated and luxurious, using sumptuous materials and emphasizing the quality in aesthetics. The essential feature was the pluralism, the multiplicity of styles, and the increasing variety of alternatives. The taste of the consumers was the result of their social status, keyed in their lifestyle and in the need of belonging to a social cultural group. It was a decade of a remarkable awareness of color, and thus color was conscientiously made the protagonist. High tech embraced industrial objects made of metal, glass, Formica, and plastic. Black made its appearance, stepping into the picture on its own, or associated with white and red, as well as with metallic colors, silver and gold, so as to emphasize the luxury effect [10, 12].

In the 1990s, the end of the Cold War brought about hope for the end of the nuclear menace. A new trend of thought set forward a deeper awareness of the environment in danger as much as greater concern about nature. Nature and its preservation became one of the main issues to deal with as well as a concern for health care and family life. A new conservative attitude was the most remarkable trend of this period, giving way to substantial subjects as ecology, the protective home, the enhancement of native roots and traditions, and the return to reassuring values. The new commandments were avoiding pollution, the efficient use of means and resources, the importance of quality instead of quantity, and the respect for nature. Attention was drawn in special toward

well-done high-quality work and craftsmanship. The search for true moral values was shown by the use of noble materials, and, in the choice of color, the main one was that of unbleached linen. The favorite colors were those of different types of wood, earth, grain, cereals, straw, sand, stone, and grayish colors that seemed to be worn out. Everyone celebrated nature in their own way: by means of choice of material, color, or subject [13, 14].

Trends for the House of the Century

The trends take into account the desire to expend more time at home, the valorization of empty space and customization of the environment, and the awareness for the preservation of natural resources. The market increasingly focused on products for the home. The decoration is freer, and nothing is definitive. Furniture is polyvalent, with fewer objects. The consumer seeks welfare, looks for quality, and wants a more simplified life. Pragmatism and health are at the order of the day.

In the new millennium, the house gains a new dimension. Tradition and modernity coexist in harmony. Earth, fire, and water are the three basic elements inspiring styles and colors. Individuality and daily rituals of life point the products chosen [14].

The configuration of a universal culture becomes a fundamental sign. The process of globalization tends to the unification of symbols, to the disappearance of diversity. It is therefore crucial to defend the values of each culture, using its imprint, to highlight its mark in every corner of the world, each time the triumph of cosmopolitanism can delete it.

From 2000 to 2020

The first 20 years of the new century saw the internationalization of markets, which diluted cultural and individual identities, and a radical change in languages and sensitivities. The contemporary context reshuffles all codes and erases any symbolic meaning. Colors thus lose their

psychological and emotional references in an operation of on-going recontextualization. All levels of consumption – the proposals of designers, fashion houses, brands, specialized magazines and the web – are increasingly subverted with an eclecticism that acts without suggestions from above and in which entropy has become the rule of color [15].

Definition

Color vision testing is the assessment of chromatic discrimination ability and the diagnosis of any perceptual deficiency according to its severity and quality (► [Protanopia](#); ► [Deutanopia](#); ► [Tritanopia](#); Genetics of Color Vision). Tests vary in sensitivity, specificity, ease of use, and time required for administration [1–4]. Many were designed primarily for vocational screening for congenital deficiency, an issue in any occupation where color-coding conveys information (e.g., railways, aviation, electronics) [5]. Testing is also important for assessing and monitoring acquired color abnormality, appearing as a manifestation of visual system pathology resulting from ophthalmological diseases (e.g., glaucoma, ocular hypertension) [6], systemic or neurological diseases (e.g., diabetes [6], Parkinson's), or the effects of medications or exposure to environmental/occupational toxins (► [Color Perception and Environmentally Based Impairments](#)).

Color vision tests fall into several broad categories [1–4]. Pseudoisochromatic plates and arrangement tests both directly address an observer's confusions between color pairs along a given confusion axis. Both types of tests have the advantage of rapid administration and ease of interpretation, making them suitable for field/epidemiological applications. Generally, they distinguish between the protan, deutan, and tritan forms of deficiency. Their results emphasize a

dichotomous outcome: whether an observer's color sensitivity is (vocationally) impaired. Versions of the tests exist for testing color vision in children. More recent computerized developments measure variations in color perception along a continuous range. Matching tests and naming (lantern) tests follow different principles. Below, the most widely used tests are described in more detail.

Pseudoisochromatic Tests

Pseudoisochromatic tests (Fig. 1) (► [Pseudoisochromatic Plates](#)) are irregular mosaics of small circles, randomly varying in size and luminance. Color differences among the circles demarcate a foreground design (digits, simple geometric forms, or curved lines), so that for a normal trichromatic observer the design stands out by Gestalt fusion from its background. In diagnostic plates the defining color difference disappears for color-deficient observers, and the design vanishes or is supplanted by an alternative design, demarcated by a different chromatic distinction. The spatial fluctuations in the mosaic mask any residual luminance traces of the normal design.

The Ishihara test, used most widely, is intended for diagnosis of congenital red-green deficiency ("daltonism"), differentiating its two types, protans and deutan, and severity (mild, moderate, or extreme) [2, 3, 8] (► [Protanopia](#); ► [Deuteranopia](#)). The Hardy-Rand-Rittler (HRR) test contains additional six plates designed to detect tritan defects and gauge their severity [8, 9]. There also exists a Farnsworth F2 plate designed specifically for revealing tritan abnormality (► [Tritanopia](#); ► [Color Perception and Environmentally Based Impairments](#)).

Color Arrangement Tests

Arrangement/panel tests use a set of color stimuli ("caps") which sample a color circle (► [Color Circle](#)) at regular intervals. The subject is requested to arrange them in sequence, so that

Color Vision Testing, Fig. 1 Examples of pseudoisochromatic plates used for screening for red-green deficiency (*top*) and tritan defects (*bottom*). (Source: Jägle et al. [7], Fig. 6.2. Springer Copyright Clearance Center. License Number: 3655300610668)

each color lies between the two colors most similar to it. Transpositions of the caps, departing from a normal trichromat's sequence, are recorded as errors. These departures can be plotted graphically to measure the angle of the confusion axis (if any) and summed to quantify the severity of any deficit.

The classical example is the Farnsworth-Munsell 100 hue (FM100) test [1–4, 9, 10], consisting of 85 caps, which takes 20–30 min to complete. Errors (transpositions) peak in the sectors of the color circle running tangential to the protan, deutan, or tritan confusion axis (Fig. 2). Performance on the FM100 improves with

Color Vision Testing,

Fig. 2 Example of the Farnsworth-Munsell 100 hue test scoring sheet indicating a moderate color discrimination defect. (Source: Jameson [11], Online Supplementary Material, p. 4, Fig. 3; <http://www.glimpsejournal.com/2.3-KAJ.html>. Copyright (2009) Kimberly A. Jameson, All Rights Reserved)

repetition, and as well as measuring color discrimination, it is affected by general nonverbal intelligence [12].

Two shorter versions, the Farnsworth Dichotomous D-15 test and the Lanthony desaturated D-15d, each contain only 15 movable caps plus a fixed “pilot cap” as the start of the sequence [10] and take about 5 min to complete. The D-15 is designed to diagnose moderate to severe color defects. The D-15d test uses color samples that are lighter and paler [13]. It was designed specifically to capture mild or subclinical color defects in observers who pass the standard D-15 test. Errors can include diametrical circle-crossing transpositions, indicating the protan, deutan, or tritan confusion axis when plotted graphically (see Fig. 1 in ► [Color Perception and Environmentally Based Impairments](#)). Outcomes of both tests can be summarized as a color confusion index (CCI), where 1.0 corresponds to perfect color arrangement and CCI values greater than 1.0 indicate progressive impairment of color discrimination [2]. These tests are often used in

conjunction, though the more sensitive D-15d is widely employed for early detection of mild acquired dyschromatopsias.

The Lanthony New Color Test [3, 4] comprises 4 panels of 15 caps each at 4 levels of saturation, to examine color similarities at 4 different scales. Like the D-15d, it can be used to track the progression of acquired dyschromatopsias.

Although not strictly an arrangement test, the City University Test [2–4] is derived from the D-15. It is a forced-choice test consisting of ten panels, each presenting four colored dots in a quincunx; the observer has to indicate which of the four colors most closely resembles the central one. The colors are selected so that protan, deutan, or tritan deficiencies affect which dot is subjectively most similar to the center.

Anomaloscopes

Within color-matching tests, the “gold standard” of color deficiency diagnosis is anomaloscopes,

Color Vision Testing,

which present colors as monochromatic lights rather than on a computer monitor or via reflective pigments. Compared to the pseudoisochromatic and panel tests, anomaloscopy requires a skilled examiner.

The Nagel anomaloscope is intended for assessment of red-green discrimination (Fig. 3). The observer views a 2° hemipartite circle, where one half is yellow light (589 nm) while the other half-circle mixes red (670 nm) and green light (545 nm) – known as the Rayleigh equation [1–3]. These wavelengths differ only in their relative stimulation of L- and M-cones (S-cones being unresponsive in this spectral range) (► [CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams](#)). A normal trichromat's setting is characterized by a green/red ratio around 41 (on a scale between 0 and 73) and a very narrow range of such settings upon retest. Anomalous trichromats accept a wider than normal range of mixed lights as indistinguishable from the yellow, with the range – from narrow to very broad – characterizing mild, moderate, or extreme impairment. A dichromat can match *any* red/green ratio to the yellow light by adjusting the luminance of the latter, which a protanopic dichromat dims if the mixed light is mainly red whereas a green-dominated light requires a more luminant yellow; the opposite is observed for a deuteranope (► [Protanopia](#); ► [Deuteranopia](#)).

The Moreland anomaloscope serves to assess tritan discrimination. One half of the 2° hemipartite circle is a cyan standard (480 nm

light tinged with a small admixture of 580 nm), which must be matched by mixing indigo (436 nm) and green light (490 nm) in the other half-circle, known as the Moreland equation [14]. Decreasing discrimination along the tritanopic confusion lines increases the range of mixtures which perceptually match the standard. Notably, at 8° only complete tritanopes accept the full range of color mixtures as a match to the cyan standard (► [Tritanopia](#)).

Computerized Tests

More recently, computerized equivalents of pseudoisochromatic tests have become common, displaying a series of colored mosaics in which the elements vary in luminance spatially as well as dynamically to leave only chromatic cues. Employed on a calibrated monitor under strict psychophysical protocols, the tests allow precise measurement of chromatic sensitivity.

In the Cambridge Colour Test (CCT) [15] (Fig. 4a), the design in each display is a stylized letter “C” with a four-way choice for the orientation for the letter's open side (► [Protanopia](#); ► [Deuteranopia](#); ► [Tritanopia](#)). The magnitude of the color difference demarcating each design (i.e., the difficulty of the choice) varies interactively in response to the observer's ongoing performance, to specify the direction in the color plane of elevated thresholds and to “bracket” their discrimination in the frame of the CIE ($u'v'$)

Color Vision Testing, Fig. 4 The Cambridge Colour Test. (a) An illustration of chromatic targets, Landolt “C”, embedded in the luminance noise background. (b) Confusion vectors (in CIE 1976 $u'v'$ chromaticity diagram) along which the chromaticity is varied in the CCT Trivector test: protan (red), deutan (green), and tritan (blue). The origin of the vectors indicates chromaticity coordinates of the

neutral background ($u' = 0.1977, v' = 0.4689$). (c) Examples of chromatic discrimination ellipses for normal trichromats: Ellipse 1 (middle), Ellipse 2 (top), and Ellipse 3 (bottom); crosses indicate raw discrimination vectors; fitted ellipses are shown by solid lines. (Fig. 4a, c: Source: Mollon and Regan [13], p. 4. Permission has been obtained from Prof. John D. Mollon, who holds the copyright)

1976 chromaticity diagram (► [CIE \$u', v'\$ Uniform Chromaticity Scale Diagram and CIELUV Color Space](#)). Outcomes are chromatic discrimination thresholds along the protan, deutan, and tritan confusion lines (Trivector test (Fig. 4b)), and elongation/orientation parameters of three MacAdam ellipses (Ellipses test (Fig. 4c)). CCT

normative data for normal trichromats for eight life decades track the impact of age upon chromatic discrimination [16]. The CCT has been employed in numerous clinical studies for differential diagnostics of relative damage to chromatic pathways [6].

Color Vision Testing,

Fig. 5 An illustration of the Colour Assessment and Diagnosis (CAD) test (right). Direction-specific, color-defined moving stimuli must be detected against a background with random, dynamic luminance contrast. (Source: Barbur and Rodríguez-Carmona [18], P. 52, Fig. 2.13(a, b). The authors hold the copyright; permission has been obtained from Prof. John Barbur)

The Colour Assessment and Diagnosis (CAD) test [5, 17] employs spatiotemporal luminance contrast masking. Direction-specific, color-defined moving stimuli must be detected against a background of random, dynamic luminance contrast (Fig. 5, right). Chromatic sensitivity is measured in 16 color directions in the CIE (x,y) 1931 chromaticity diagram. From these, mean thresholds are computed for the red-green and blue-yellow systems (Fig. 5, left) (Color Vision, Opponent Theory), to diagnose accurately the observer's class of color vision (i.e., normal, protan-, deutan-, tritan-like congenital loss, or acquired color vision deficiency). The CAD units of chromatic sensitivity are based on the mean thresholds measured in 333 young normal trichromats; they also serve as the reference for threshold estimates in normal aging [17]. The CAD test has been extensively applied for screening in occupations with visually demanding tasks that imply efficient chromatic discrimination [5] and in clinical practice [6].

“Electrodiagnosis” Tests

An alternative to behavioral testing is “electrodiagnosis” of congenital color vision deficiency, which measures retinal and cortical responses to stimulation, using standard electrophysiological

methods of electroretinogram (ERG) and visual evoked potential (VEP) recordings, respectively. Both forms of measurement show promise for detecting cone dysfunction. With a silent substitution paradigm to probe each cone type in isolation [19], L-cone stimulation evokes no ERG responses in protanopes (► [Protanopia](#)), while responses to M-cone stimuli are greatly reduced in deuteranopes (► [Deutanopia](#)); VEP amplitude is reduced in both classes of dichromats.

A second paradigm uses heterochromatic flicker stimulation, at high frequency (36 Hz) or intermediate frequency (12 Hz) to isolate the parasol-ganglion cell or midget cell retinal responses, respectively (i.e., luminance summation or chromatic opponency), while varying the counterphase red- and green-flicker contributions to overall stimulation [20]. The diagnostic parameters (luminance response fraction and L-cone response fraction) were found to reliably distinguish normal trichromats, protanopes, and deuteranopes.

Notably, in both paradigms, diagnoses have been confirmed by chromatic discrimination thresholds (measured with the Cambridge Colour Test) and genetic analysis of L- and M-opsin genes. The new diagnostic approach provides evidence of cone-specific ERGs and VEPs as reliable methods to detect congenital cone dysfunction.

Definition

The environmental characteristics of colorants (dyes and pigments) encompass topics pertaining to the impact of such compounds on human health and biota. This is important because as much as 15% of the commercially used colorants reach the environment – mainly through the release of effluents into aquatic and soil biota. Humans can be exposed to various colorants or their transformation products often through drinking water and through dye and pigment manufacturing processes [1]. Therefore, it is important to have information pertaining to the toxicity of colorants as well as their possible transformation products, to avoid unacceptable health risks. In the case of dyes, the principal sources of losses are colorants remaining in dyebaths following textile dyeing processes. Another area of concern arises from the use of sludge from waste treatment plants as soil amendments, leading to possible soil contamination. Thus, methods pertaining to the treatment of industrial wastewater prior to the release of effluents have been developed, along with other pollution prevention methods, as key components of environmental stewardship.

Overview

The environmental properties of colorants are often determined by employing a battery of tests that are concerned principally with the potential for mutagenicity, carcinogenicity, and aquatic toxicity. An overview of developments in these areas is presented.

Mutagenicity

Some dyes are known to exhibit mutagenicity, and the most commonly used test for assessing mutagenicity potential is the reverse mutation assay employing specially engineered *Salmonella* bacteria. The standard *Salmonella*/mammalian microsome assay, often called the Ames test, is the most widely used protocol as an initial screening test procedure for assessing the mutagenic potential of new compounds. It was introduced in 1975 by Ames and co-workers [2], who observed that most mutagens were also carcinogens and that the extent of a compound's mutation of DNA was related to its carcinogenic potential, due to the susceptibility of DNA to chemical mutagenesis. Nowadays, the correlation between mutagenicity in the Ames test and carcinogenicity seems to be >60%.

The Ames test is an in vitro method that commonly uses one or more strains of *Salmonella typhimurium*. There are six strains of *Salmonella typhimurium* that are widely used in a mutagenicity test and are designed to detect different types of mutations involving colorants. TA98 and TA1538 are sensitive to frameshift mutagens, TA100 and TA1535 are used to detect base pair substitution mutations, and TA97 and TA1537 are used for frameshift mutations, which sometimes cannot be detected with the former strains. Also other strains such as YG1041, derived from TA98, have been employed because of high sensitivity to dyes containing nitro (NO₂) or amine (NH₂) groups. These strains cannot produce the amino acid histidine, an essential component for growth. Thus, the bacteria are unable to multiply unless a

mutagen causes the proper type of reverse mutation in the histidine gene. Mutagenic activity can be measured quantitatively by simply counting the number of colonies present after incubating *Salmonella* bacteria with several doses of the test compound and other necessary test additives for a standard length of time.

The change in the bacteria that permits growth is called a reverse mutation, and the colonies that form are called revertant colonies. Generally, the test compound is considered mutagenic when the number of revertant colonies is more than twice that of the base count. Based on the number of the revertant colonies produced, the compound is characterized as a non-mutagen, a weak mutagen, or a strong mutagen. A solvent is added to facilitate adequate mixing, and an enzyme mixture may also be added to metabolize the test compound to enhance the sensitivity of the test, since bacteria do not have some of the enzymes present in mammalian tissues. The enzyme mixture is important

because many compounds are mutagenic once they are metabolized in the liver and other tissues. An exogenous metabolic system usually rat liver microsomal enzyme system, S9, is used in the *Salmonella* microsome mutagenicity assay.

Benzidine-based dyes such as C.I. Direct Black 38 (Fig. 1) are carcinogenic in several mammalian species. However, certain benzidine-based dyes (e.g., 1; C.I. Direct Red 28; Congo Red) are not mutagenic in the standard *Salmonella* microsome test. Consequently, the standard test was modified in 1982 to ensure the liberation of the parent diamine (cf., 2→4; Fig. 2) and the maximum possible mutagenic activity in each of the benzidine-based azo dyes studied [3]. This is an important protocol for benzidine-based dyes and is known as the preincubation assay (Prival modification) under reductive conditions, a test that employs hamster liver S9 which is believed to be richer in azoreductase enzymes.

Colorant, Environmental Aspects, Fig. 1 Molecular structure of C.I. Direct Black 38 (1)

Colorant, Environmental Aspects, Fig. 2 Reductase enzyme cleavage of C.I. Direct Red 28 liberating carcinogenic benzidine (4)

As a follow-up to positive Ames/Prival outcomes, *in vitro* testing such as a gene mutation assay involving mammalian cells or the mouse lymphoma test, a chromosome aberration assay, has been recommended [4]. This approach complements the mutagenic evaluation of a compound, providing a more accurate prediction of its mutagenic properties and carcinogenic potential.

Carcinogenicity

Although a variety of synthetic colorants have been studied, the majority of our knowledge and major concerns in this area arises from the recognition of azo dye manufacturing involving benzidine and 2-naphthylamine as a source of bladder cancer in humans. This soon led to extensive evaluation of azo dyes and their precursors for carcinogenic potential. The volume of results from work in this area became so substantial and diverse that a concerted effort to digest it has been made [5]. A key goal was to determine (1) whether the production of tumors in animal studies was sufficient to designate a dye as a human carcinogen and (2) the reliability of the published literature. This inspired an assessment of published data on a group of 97 representative azo colorants associated with the dyestuffs industry, for the purpose of determining the scientific standing of the experimental work in this area and the potential human hazard associated with these compounds. This assessment contributed to a set of recommended guidelines for carcinogenicity testing that cover chemical purity of test compounds, number of animals tested and survival rates, study controls, dose levels, route of administration, duration of experiments, pathological considerations, number of species, and evidence of human carcinogenicity. Application of the guidelines to published data afforded six categories of animal carcinogens and noncarcinogens:

1. Class A – the colorant was tested in at least two species of animals, resulting in the generation of nonconflicting data, using a sufficient number of animals (25 per group) and having a sufficient number of survivors for about two-thirds their expected lifetime. Repeated

injections and urinary bladder implantations should not be regarded as meaningful in the context of chemically induced neoplasia. For a positive response, a target organ was identified and the induced tumors diagnosed as malignant.

2. Class B – the colorant was tested according to Class A guidelines, but meaningful data was generated for one species only.
3. Class C – testing of the colorant involved an insufficient number of test animals, and/or too many premature deaths occurred for results to be conclusive. For a positive result or trend, an increase in the number of animals with malignant tumors was observed but a target organ not identified.
4. Class D – the colorant was tested in multiple animal assays, which individually did not permit a conclusion but taken together provide sufficient evidence for an opinion.
5. Class E1 – the colorant was tested in a method considered inappropriate for evaluation of chemical carcinogenicity, e.g., by bladder implantation or using too few animals.
6. Class E2 – there was insufficient data to permit a rational judgment regarding carcinogenicity.

Structure-activity relationships associated with azo dye carcinogenicity produced the groupings depicted in Figs. 3, 4, 5, 6, 7, and 8 [6]. Group 1 comprises carcinogenic azo dyes that are hydrophobic (lipophilic) colorants having a 4-aminophenylazo base structure (5–8; Fig. 3) [7]. As illustrated in Fig. 4, the 4-amino group is susceptible to a series of metabolic steps leading to an electrophilic nitrenium ion (6→11) that can react with DNA. This illustration is important because it serves as a reminder that azo bond cleavage is not an absolute requirement for genotoxicity. Group 2 examples in Fig. 5 show that placement of the amino group ortho to the azo bond rather than para can lead to a nitrenium ion having an internal mechanism for deactivation (cf., 12→15). Group 3 comprises azo dyes producing one or more carcinogenic aromatic amines, upon cleavage of the azo bonds that are designated as carcinogenic, examples of which are shown in Fig. 6. In these examples, 2,4-dimethylaniline, 2,3,4-trimethylaniline, and

formation

benzidine are produced by cleavage of the azo bonds in **16–18**. The properties of this dye grouping led to a ban on commercial products containing dyes derived from any of the family of 22 aromatic amines (now 24) known to be carcinogenic [8]. Similarly, dyes metabolized to

benzidine are now classified by the IARC (International Agency for Research on Cancer) as belonging to Group 1 (carcinogenic to humans) [9, 10].

Group 4 azo dyes are metabolized to noncarcinogenic sulfonated aromatic amines and are

Colorant, Environmental Aspects, Fig. 6 Azo dyes in Group 3 that liberate a carcinogenic aromatic amine upon reductive cleavage

Colorant, Environmental Aspects, Fig. 7 Azo dyes in Group 4 that liberate noncarcinogenic sulfonated amines upon reductive cleavage

regarded as safe to use (19–20). These structural types include FD&C Red 4 (19; Fig. 7), as well as FD&C Yellow 5 (Tartrazine, C.I. Food Yellow 4) and FD&C Yellow 6 (C.I. Food Yellow 3) [11]. Due to its benign nature, C.I. Food Black 2 (20) was the first black dye used for ink-jet printing and has long been a prototype for designing improved black dyes for this end-use area [12].

Insoluble organic pigments such as 21–22 characterize Group 5 colorants, which are non-carcinogenic (Fig. 8). They are not readily metabolized to their diamine precursors or absorbed into mammalian systems. The principal

requirement for safety among organic pigments is the control of the concentration of unreacted (free) aromatic amine precursors in the commercial product [13].

Aquatic Toxicity

Aquatic toxicology is the study of the deleterious effects of chemicals such as colorants on aquatic organisms. The associated tests may be used to measure the degree of response produced by exposure to various concentrations of dyes and pigments and may be conducted in the laboratory

Colorant, Environmental Aspects, Fig. 8 Examples of noncarcinogenic highly water-insoluble azo pigments in Group 5

or field. In the USA, the Clean Water Act (cf. Title 40 of the US Code of Federation Regulations 100–140, 400–470), which is administered by the Environmental Protection Agency (EPA), limits water pollution from industrial and public sources, stresses the importance of controlling toxic pollutants, and encourages investigations leading to waste treatment technologies [13]. Similarly, the Office of Pollution Prevention and Toxics (OPPT) implements the Toxic Substances Control Act (TSCA) as part of its responsibility for evaluating and assessing the impact of new chemicals and chemicals with new uses, to determine their potential risk to human health and the environment. Testing recommended includes acute and chronic toxicity for assessing environmental effects and bioconcentration, biodegradation, physicochemical properties, and transport/transformation studies for assessing environmental fate [14, 15].

Ecosystem-related toxicological testing includes acute and chronic toxicity tests employing species such as fish, *Daphnia*, algae, earthworms, and others. The overall goal is to determine the potential for changes in the composition of plant or animal life, reduction in reproductive success or the robustness of a species, alteration in the behavior or distribution of a species, and long-lasting or irreversible contamination of components of the physical environment (e.g., surface water). Specifically, acute toxicity tests are short-term tests designed to measure the effects of toxic agents on aquatic species during a short period of their life span. Acute toxicity tests

evaluate effects on survival over a 24- to 96-h period. Chronic toxicity tests are designed to measure the effects of toxicants to aquatic species over a significant portion of the organism's life cycle, typically one-tenth or more of the organism's lifetime. Chronic studies evaluate the sublethal effects of toxicants on reproduction, growth, and behavior due to physiological and biochemical disruptions.

The most common acute tests are performed with daphnids, mysid shrimp, amphipods, and fish (e.g., fathead minnow, zebrafish, and rainbow trout). Chronic tests are often used for life-cycle studies using *Ceriodaphnia dubia* (7 days) and *Daphnia magna* (21 days). LC50 (lethal concentrations 50%) are defined as the test concentrations at which 50% of the test organisms are dead after a certain time of exposure. For fish [16], some examples of LC50 values obtained for dyes were 0.047 mg/L for C.I. Basic Violet 1 (methyl violet), 0.12 mg/L for C.I. Basic Green 4 (malachite green), 1 mg/L for Disperse Blue 3, 3.2 mg/L for Basic Yellow 11, 4 mg/L for C.I. Basic Blue 3 and C.I. Acid Blue 113, 5.6 mg/L for C.I. Basic Brown 4, 5 mg/L for C.I. Mordant Black 11, 6.2 mg/L for C.I. Acid Green 25, and 7 mg/L for C.I. Acid Black 52. These commercial products included 29 of the 47 dyes with LC50 >180 mg/L, many that were bisazo or trisazo dyes. Three dyes had LC50 values between 100 and 180 mg/L, and the remaining 14 had values <100 mg/L. These results are consistent with the frequent lack of correlation between the genotoxicity and aquatic

toxicity of organic colorants. Whereas benzidine-based dyes such as C.I. Direct Black 38 (1) and C.I. Direct Blue 6 (18) are designated as carcinogenic, they did not exhibit acute toxicity when tested with aquatic organisms, along with their counterparts **23–24**, both of which are Cu complexes (Fig. 9).

On the other hand, all of the cationic (basic) dyes (**25–28**) and anthraquinone disperse and acid dyes (**29–31**; Fig. 10) were significantly, if not extremely, toxic in this assay. Interestingly, bisazo dye C.I. Acid Blue 113 (**32**), unlike the bisazo direct dyes, unmetallized precursor C.I. Mordant Black 11 (**33**, Fig. 11), and its Cr-complex C.I. Acid Black 52 (**34**) were also significantly toxic. Water-insoluble vat dyes (**35–37**; Fig. 12) did not exhibit acute toxicity in this assay. Clearly, more studies are needed in this area in order to establish correlations between the molecular structures of colorants and their aquatic toxicity. While the picture is somewhat clearer regarding cationic dyes and vat dyes, it is much less so regarding sulfonated azo dyes. In a study involving the sparingly water-soluble monoazo dye C.I. Disperse Red 1, aquatic toxicity was observed in a variety of aquatic animals, and the microcrustacean *Daphnia similis* was the most sensitive species in acute and chronic toxicity tests [17]. In this study a risk assessment was performed. Acute and chronic water quality criteria were calculated

based on the toxicity tests. River water samples were analyzed during the 4 seasons of the year, and Disperse Red 1 was detected in 6 of the 14 samples. The concentrations varied from 50 ng/L to 500 ng/L. No acute risk was verified for any of the samples, but chronic risk was detected in five of the six samples [17]. Although dyes have been typically found in the aquatic environment and concentrations are in the ng/L range [18], it is important to have a comprehensive assessment of their hazard for a proper risk assessment evaluation.

Bioconcentration studies are performed to evaluate the potential for a chemical to accumulate in aquatic organisms that may subsequently be consumed by higher trophic-level organisms including humans. The extent to which a chemical is concentrated in tissue above the level in water is referred to as the bioconcentration factor (BCF). It is widely accepted that the octanol/water partition coefficient (e.g., Log K_{ow} or Log P) can be used to estimate the potential for nonionizable organic chemicals to bioconcentrate in aquatic organisms.

With regard to water quality concerns, a variety of methods have been developed to treat wastewater prior to industrial discharges, in order to remove colorants that are clearly visible at very low levels (e.g., 1 ppm). The methods employed involve chemical and biological agents for reduction and oxidation, physical adsorption,

Structures of compounds 38–39

membrane filtration, precipitation, and recycle and reuse. The latter methods are especially important since dyes are engineered to be stable compounds under end-use conditions and thus are completely decomposed with considerable difficulty. Also, care must be used when choosing a wastewater decoloration method. In several countries, effluents from biological treatment are decolorized using chlorine for simultaneous pathogen removal. It has been found, however, that the chlorination of wastewater containing certain disperse dyes can generate mutagenic compounds known as phenyl-benzotriazoles (PBTAs; **38**). These chlorinated compounds have been observed in drinking water. Similarly, the chlorination of commercial C.I. Disperse Red 1 (**39**; Fig. 13) produced higher mutagenicity than the untreated dye [19].

Future Directions

Bearing in mind that organic colorants include naturally occurring and synthetic compounds

and that the major concern generally lies with the latter types, there is renewed interest in exploring natural dye-based coloration processes because such dyes are widely regarded as biodegradable and of low inherent toxicity. In fact, various natural dyes are part of a normal diet (e.g., beta-carotene and lycopene, both of which are important antioxidants). Although few natural colorants have shown commercial viability (e.g., indigo, madder, logwood), they continue to find success in niche areas such as arts and crafts and enjoy exploration for potential use in mainstream products. It is worthwhile pointing out that the use of natural dyes as colorants for textiles often introduces the need for additives known as mordants, to help bond these dyes to fibers, since natural dyes have very low affinity for textiles. Mordants such as Cu and Cr are toxic to aquatic life and pose human health risks, making Al and Fe better choices. Regarding synthetic colorants, which encompass water- and/or solvent-soluble organic dyes and insoluble organic and inorganic pigments, they will continue to be the primary agents for adding color to substrates such as

natural and synthetic fibers, paper, plastics, petroleum products, printing inks, hair, and food, drug, and cosmetic products. Due to their practically insoluble nature, pigments have very low bioavailability; hence much of the attention in the area of environmental concerns has fallen on synthetic dyes. Among the synthetic dyes, azo dyes lie at the forefront in this area, and the choice of such dyes will continue to take into consideration the environmental properties of the required precursors and the metabolites formed in mammalian systems.

Definition

The term natural colorant comprises all kind of materials available from natural sources which are able to impart color to matter.

The main principle of color development for natural colorants is the specific absorption of light in the wavelength region of 400–700 nm [1].

Other principles on color formation may be based upon physical effects, for example, refraction of light (rainbows), interference (feathers of peacocks), or electron excitation (electroluminescence) [2].

Sources for natural colorants include minerals (red ochre, $\alpha\text{-Fe}_2\text{O}_3$), plant material (e.g., flavonoids from Canadian golden rod), and animal-based dyes (e.g., indigoid colorants from selected mollusk species).

Colored pigments are applied as finely divided solid particles which remain in an insoluble state during their application and use. Water-soluble or oil-soluble natural colorants can be found in food and beverage applications. A colorant that is used as dye must exhibit a specific substantivity towards that substrate. A dye is thus able to be sorbed at the surface of the material. Basic interactions lead to dyestuff sorption and binding on the material to be dyed are covalent binding, ionic attraction, π -bonding interaction, hydrogen bonding, and Van der Waals attractions [3]. With exception of covalent binding all other principles of dyestuff fixation are found in application of natural colorants.

According to structure, organic natural colorants can be divided into several main groups, namely, flavonoid dyes (including anthocyanins), substances containing naphthoquinoid and anthraquinoid groups, indigoid dyes, tannins, carotenoids, and chlorophylls [4].

The colorant content in natural sources is relatively low, usually of the order of a few % of the dry material. Thus, considerable amounts of raw material have to be processed.

Natural colorants are usually obtained by means of aqueous extraction of plant material; the use of solvents is less common as substantial amounts of plant material have to be extracted. As a result of the nonselective extraction process,

natural colorants usually contain a number of different color-providing chemical substances. The classification of a dye plant or animal source to a certain group of colorant usually is based on the properties of the most important species of dye present in the extract.

Major applications of natural colorants are as the coloring elements in food, as dyes for traditional textile dyeing eco-textiles, and as pigments for cosmetics [5].

Natural colorants can be applied in different ways. In many cases the extracted dye can be used directly (e.g., food and selected textile applications), but often mordants are used to increase dye adsorption (e.g., for textile dyeing and dye-lake formation). Important mordanting substances are tannins or metal salts. Due to ecological requirements mainly iron and aluminum salts are used as metal-based mordants.

Major Classes of Natural Colorants

As mentioned, as a result of the extraction of natural colorants from native sources, with few exceptions, a number of colored substances are present in the extract, and, therefore, natural colorants are classified on the basis of the main constituent, which is of relevance for a given application. Important dyes with known chemical structure have been assigned color index (C.I.) generic names and/or C.I. constitution numbers. The major classes of colorant are discussed below.

Indigoid Dyes

The two most important natural dyes of indigoid structure are indigo (C.I. Natural Blue 1) obtained from plant sources and Tyrian purple (6,6'-dibromoindigo, C.I. 75800) from the Muricidae family, e.g., spiny dye murex (*Bolinus brandaris*) or banded dye murex (*Hexaplex trunculus*).

The structures of these two dyes are given in Fig. 1.

Tyrian purple is found in extracts from the hypobranchial glands of the gastropod mollusk. While the applicatory properties and fastness of the colorant were generally acceptable, the use of

Colorant, Natural,**Fig. 1** Structure of indigo (left) and Tyrian purple (right)**Colorant, Natural, Table 1** Indigo plants

Plant	Botanical name	Climate	Region	Precursor
Indigo plant	<i>Indigofera tinctoria</i> L.	Tropical	India, Africa, and North, Central, and South America	Indican indigo- β -d-glucoside
Woad	<i>Isatis tinctoria</i> <i>Isatis indigotica</i>	Temperate	Europe, China	Isatan B indoxyl-5-ketogluconat
Dyer's knotweed, Ai	<i>Polygonum tinctorium</i> AIT	Subtropical and temperate	Europe, Japan	Indican indigo- β -d-glucoside

this dye ceased due to the low dye content in the mollusk.

Indigo is the most relevant blue natural dye and different plants have been cultivated for indigo production all over the world. As a general rule, the indigo is present in the plant in the form of different colorless indoxyl glycosides as precursors. Selected plants for indigo production are summarized in Table 1. The indigo precursor indoxyl also can be synthesized by microbiological methods [6].

To obtain indigo the precursor is first hydrolyzed enzymatically to obtain the intermediate indoxyl, which then rapidly oxidizes in the presence of air oxygen to indigo. The precipitated solid indigo dye then can be collected. The oxidation of indoxyl to yield the yellow isatin is an unwanted side reaction, which can cause substantial losses in indigo yield. A general scheme is presented in Fig. 2.

Besides the use as insoluble indigo colorant, indigoid dyes usually are applied as vat dyes. In vat dyeing the insoluble dye (indigo) is firstly converted to the alkali-soluble leuco form, which exhibits substantial substantivity towards protein fibers (wool and silk) and cellulosic fibers (cotton, flax, and regenerated cellulose fibers). The adsorbed reduced indigo dye (yellow) is then oxidized to generate the blue-colored insoluble form of the colorant using air or chemical oxidants. For deep shades, the procedure of immersion into the

**Colorant, Natural, Fig. 2** Main steps in production of natural indigo (R = glycosidic bond carbohydrate)

leuco dye bath and subsequent oxidation in air is repeated several times.

Dye reduction can be achieved by use of reductants and alkali, such as sodium dithionite ($\text{Na}_2\text{S}_2\text{O}_4$) or reducing sugars and NaOH ; alternatively, anaerobic microbial reduction can be employed. Microbiological dye reduction is practiced in traditional handicraft dyeing, but up to now is not applicable for dyeing with indigo in denim production (jeans).

Flavonoids and Anthocyanins

Flavonoids contribute to the color of many food products and thus are consumed by humans in the form of fruits and food. The color gamut provided by these colorants ranges from the yellow flavonoids (e.g., flavonols, chalcones, and aurons) to orange–red–purple anthocyanins. In plants many flavonoids are present as glycosides; anthocyanins are also glycosides, while the respective aglycones are named anthocyanidins. Representative structures of flavonoids and anthocyanidins are given in Fig. 3.

Yellow flavonoid dyes can be extracted from a high number of plant sources; selected representatives are given in Table 2 [7].

For textile dyeing, flavonoids can be used as direct dyes or as mordant dyes in combination with metallic mordants such as Fe or Al salts. When Fe, Sn, or Cu salts are employed as mordants, metal complexes are formed and a distinct change in color is observed, e.g., olive shades are obtained when an onion extract is applied in combination with Fe mordant.

The range of colors of anthocyanin dyes is of high coloristic interest for application as food colorants and for general purposes of coloration. The limited stability of the molecules can be improved by co-pigmentation, metal complexation, and the use of additives. Dependent on solution pH, anthocyanins rearrange to form different

species with different absorption spectra. Some of these products are colorless which explains the propensity of the colorants to fade.

A general scheme describing the pH-dependent rearrangement of an anthocyanin structure is given in Fig. 4.

At pH 1.0, orange–red/violet oxonium/flavylium ions are present which are of greatest stability (Fig. 4, AH⁺). With increase in pH to between 4 and 6, the colored quinoid base appears (Fig. 4, A). At the same time the formation of the colorless hemiketal (Fig. 4, B) gains importance. The hemiketal B is sensitive to tautomerization and ring opening, thereby leading to colorless cis- and trans-chalcone forms (Fig. 4, Cc and Ct) [8].

Stabilization of the dye molecules can be achieved by co-pigmentation. By inter- and intramolecular complex formations, self-association, and metal complex formation, the stability of the dyes can be increased; in many cases the color becomes bluer (bathochromic shift) and absorbance is increased (hyperchromic shift).

Anthocyanins are found in many intensively colored fruits and berries. Examples are summarized in Table 3.

Quinoid, Naphthoquinoid, and Anthraquinoid Dyes

Important yellow, orange, and red dyes belong to this group of colorants.

Colorant, Natural, Fig. 5 Structure of carthamin

The red–orange quinoid dye carthamin (C.I. Natural Red 26) can be obtained by extraction of blooms of safflower (*Carthamus tinctorius*) (Fig. 5).

Two important representatives of naphthoquinone dyes are lawson (2-hydroxy-1,4-naphthoquinone) and juglon (5-hydroxy-1,4-naphthoquinone) (Fig. 6).

Colorant, Natural, Fig. 6 Structures of lawson (left) and juglon (right)

Lawson (C.I. Natural Orange 6) is extracted from henna (*Lawsonia inermis*). The plant grows best in tropical savannah and arid zones. The leaves contain lawson in the form of its glycoside, which hydrolyses and releases the aglycone, which then is oxidized to the quinone form. Lawson is of significant interest in hair dyeing. As a small molecule, its diffusion rate is sufficiently high to impart acceptable levels of color under the gentle conditions employed for hair dyeing. When henna leaves are mixed with leaves of the indigo plant, the so-called black henna is obtained. In the application as hair dye, lawson and indigo are fixed on the hair and brown-black shades are obtained.

Anthraquinone dyes can be extracted from plant sources (madder, *Rubia tinctorum*, C.I. Natural Red 8; *Hedge bedstraw*, *Gallium mollugo*, Natural Red 14) [9] or from animals (Kermes, *Kermes vermilio*, C.I. Natural Red 3; cochineal, *Dactylopius coccus*, C.I. Natural Red 4). Anthraquinoid dyes also have been extracted from fungi and lichen [10].

Most plant-based anthraquinoid dyes are extracted from the roots of the plants. The colorants are present as glycosides which hydrolyze during storage or extraction to the corresponding anthraquinoid dye. Representative structures (Alizarin, 1,2-dihydroxyanthraquinone, pseudopurpurin 3-carboxy-1,2,4-trihydroxyanthraquinone)

are shown in Fig. 7. Through the high number of hydroxyl groups that neighbor the quinoid system, these compounds are able to form stable metal complexes with, for example, aluminum or calcium. Thus, in traditional textile dyeing with madder extracts, mordanting with metal salts is used to improve dye fixation and fastness. The high fastness properties of such dyeings makes them valuable for textile applications, although care has to be exercised to ensure that harmful components such as lucidin (1,3-dihydroxy-2-hydroxymethyl-anthraquinone) have been removed, e.g., through an oxidation step.

Kermes, cochénille, and lac are important examples of insect-based natural colorants. In the cases of kermes and cochénille, the parasitic insects live on host plants from where the female insects are collected and dried. Lac is obtained from the secretions of the lac insect. Due to the high quality (light fastness and wash fastness) of red textile dyeings, these dyes were of high importance in traditional dyeing. The dyes still are produced in considerable amounts for cosmetic applications and as food colorants (Table 4).

Tannin-Based Dyes

Tannins are a complex group of polyphenolic compounds. Gallotannins comprise the structural unit of gallic acid esterified with sugar molecules (hydrolysable tannins), while tannins contain

Colorant, Natural,

**Colorant, Natural, Table 5** Plant sources for gallotannins and tannin agents (condensed tannins)

Plant	Name	Part of plant	Main colorants	Content/ %	Color index number
Aleppo gall on oak tree	<i>Quercus infectoria</i>	Gallnut	Turkey tannin	50–70	
Sicilian sumac	<i>Rhus coriaria</i>	Leaves, twigs	Gallotannin	23–35	C.I. Natural Brown 6
Sticky alder tree	<i>Alnus glutinosa</i>	Bark	Gallotannin	20	
Pomegranate	<i>Punica granatum</i>	Pomegranate fruit bark	Gallotannin	28	C.I. Natural Yellow 7
Scots pine	<i>Pinus sylvestris</i>	Bark	Tannin agent	17	
Cutch/catechu	—	Bark, leaves	Tannin agent	—	C.I. Natural Brown 3
Tea	<i>Camellia sinensis</i>	Leaves	Tannins agent	25	

flavan as general structural element, by condensation complex polyphenolic structures are formed (condensed tannins) (Fig. 8).

Tannins are found in all parts of plant, e.g., bark, wood, leaves, floral parts, and gallnut. In contrast to other natural colorants, the tannin content in plant material is much higher and, depending on source, can reach levels of 50% of the plant mass (Table 5).

A gallnut is formed as response to the egg deposition by a gall wasp, e.g., on a leaves and twigs of an oak tree.

The term catechu is used for a number of plant extracts with high content in tanning agents, obtained from different plants, e.g., mangroves, conifers, cutch, and acacia.

Tannins and tannin agents form intensively colored complexes with metals such as iron and copper; thus, color development usually is coupled to use of metal mordants. An important example for such a colorant is the intensively colored iron complex with gallic acid, the dark-blue colored iron gall ink.

Tannins also are used as mordants in place of metal mordants to increase the extent of

adsorption and fastness of other natural colorants. Attractive forces in tannin mordanting then are π -bond interactions, hydrogen bonding, and Van der Waals forces.

Carotenoid Dyes

A number of yellow, orange, or red pigments are found in many plants and animals. Animals are not able to synthesize carotenoids, which they have to obtain from their food.

Carotenoids are polyisoprenoids; hydrocarbon carotenoids are carotenes, while oxygen-containing molecules are named xanthophylls. Characteristically, carotenoids comprise conjugated double bonds. Typical examples are α -carotene (carrots, *Daucus carota*; red palm oil), lutein (green leafy vegetables, broccoli, corn), bixin (annatto seeds, *Bixa orellana*, C.I. Natural Orange 4), capsanthin (paprika seed, *Capsicum annuum*), lycopene (tomato, *Lycopersicon esculentum*), and crocetin (saffron, *Crocus sativus*, C.I. Natural Yellow 6) (Fig. 9).

From annatto seeds and saffron flowers, orange dyes can be obtained by aqueous extraction. The water-soluble colorants can be used to dye wool, silk, and cellulose fibers. Both dyes also are used as food colorants.

A major group of other carotenoids exhibit poor solubility in water, and extracts are obtained using solvents of low polarity (hexane, oil). As a result, their use as food colorants is dependent on the oil content of the product as in many cases the oily phase will contain the dye.

Chlorophylls

While chlorophylls represent the most abundant pigments in nature, their use as colorants is limited due to low chemical instability and high production costs. Different natural chlorophylls have

been identified (chlorophyll *a*, *b*, *c*, *d*, and *e*). While the extraction of the green dye from plant leaves, algae, appears of high interest for the coloration of food, cosmetics, and textiles, difficulties in obtaining pure products and the rapid modification via endogenous plant enzymes to brown-green products prevent the simple, direct use of chlorophyll as a colorant.

Chlorophyllines are semisynthetic, metal-chelated chlorophyll derivatives which exhibit higher stability and are water soluble in many cases. After hydrolytic treatments and replacement of the central magnesium by copper, sodium copper chlorophyllin can be obtained. In Europe the green complex can be used as colorant for sweets, ice cream, and cheese. In the USA the use of copper chlorophyllin is more restricted, a possible use being in dentifrice.

The use of copper chlorophyllin for the coloration of paper, textiles, and leather is under consideration, although the Cu content in the product has to be considered.

Applicatory Aspects

As many natural colorants are readily soluble in water, this is the main solvent used to extract the dye from a source. Due to the low content of colored material in the natural source, the amount of colorant in the extract is limited. Use of solvent extraction such as ethanol or hydrocarbons is limited to special purposes as considerable amounts of treated material, e.g., plant residues have to be deposited.

Concentration by solvent evaporation has to be considered carefully for energy reasons. Another technique to obtain concentrated dye preparations is precipitation as a dye lake by formation of insoluble complexes, e.g., by addition of calcium, iron, or aluminum salts.

Colorant, Natural,
Fig. 9 Structure of bixin
(a) and crocetin (b)

The dye lakes can be used directly as pigment dyes for paints and cosmetics.

For textile dyeing purposes, the extracted natural colorant can be used either directly without recourse to mordants. Attachment of the colorant to the substrate is then based on H-bonding, dipole interactions (Van der Waals forces).

Mordants are auxiliary chemicals used to increase dye adsorption and fixation on the substrate. The mordant can be applied in a separate bath (pre-mordanting), added directly to the dye containing bath (meta-mordanting), or used as an aftertreatment (post-mordanting).

Use of separated mordanting appears useful with regard to an efficient dyestuff consumption, however additional treatment steps and separate handling and storage of the concentrated mordanting baths make the straightforward meta-mordanting more attractive to dyehouses.

While in traditional dyeing with natural colorants, many different heavy metal salts were used (e.g., copper, tin, and chromium), environmental legislation has restricted the use of heavy metals in textile processes, and as a result, mainly iron-, aluminum-, and tannin-based mordants may be used nowadays [11].

Definition

Light is composed of an electromagnetic field that can interact with the elementary charges in matter, whose response can in turn influence the behavior of the other light waves. When light passes through any material, its electric field induces changes in the polarization of the material's molecules. In “linear” materials the degree of electron displacement, characterized by the linear polarizability α , is proportional to the strength of the applied electric field.

The distinguishing characteristic of nonlinear optical colorants is that their polarization response

to optical waves depends nonlinearly on the applied electric field strength. This can result in the emission of new radiation fields which are altered in phase, frequency, polarization, or amplitude relative to the incident optical radiation. Many of these effects are sensitive to specific characteristics of the local optical properties and interfaces. Multi-photon absorption can also result in electronic excitations that for a given incident light beam are more strongly localized in space than those resulting from linear absorption processes.

Nonlinear optical materials continue to attract the interest of both industrial and academic researchers due to their many versatile applications in the domain of optoelectronics and photonics.

Historical Background

Over the past decades, a variety of materials have been investigated for their nonlinear optical properties, including inorganic materials, coordination and organometallic compounds, liquid crystals, organic molecules, and polymers [1–10]. Nonlinear optics was born in 1875 when John Kerr discovered that the refractive index of glass and organic liquids could be altered by an applied electric field with the induced changes being proportional to the square of the applied field strength. Kerr measured, for the first time, the third-order nonlinear susceptibility, or what is today called the *Kerr effect* or the *electro-optical effect*. This discovery was shortly followed in 1883 by the observation of a similar but linear electric field effect in quartz; this latter process now referred to the *Pockels effect*. These nonlinear effects had limited use until the invention of the laser in 1960 by Maiman and, in the following year, the observation by Franken et al. of second harmonic generation in quartz. Following these events, the field of nonlinear optics developed explosively throughout the 1960s, highlighted by the work of Bloembergen and coworkers in exploring the full range of nonlinear optical responses of material systems and that of Buckingham and colleagues in exploring

nonlinear processes in atoms and molecules of interest to chemists [11].

Initially, optical communications technology used components almost exclusively based on inorganic NLO materials. At the time it was thought that these compounds were more suitable than organic compounds due to their greater chemical, photochemical, and physical stability and ease of processing. The two main classes of materials investigated were inorganic crystals of lithium niobate (LiNbO_3) and barium titanate (BaTiO_3) or semiconductors such as gallium arsenide (GaAs) or zinc selenide (ZnSe). Electro-optical devices that use lithium niobate have been on the market for several decades. However, these crystals have several drawbacks: high-quality single crystals are difficult to grow, are expensive, and are not easy to incorporate into electronic devices. During the 1980s it became clear that organic materials might be a better choice for use in nonlinear optical applications. A lot of organic compounds exhibit extremely high and fast nonlinearities, much better than those observed in inorganic crystals. In addition, due to the versatility of organic synthesis, their nonlinear optical properties can be modified depending on the desired application. Furthermore, organic chromophores can be incorporated into a variety of macroscopic structures such as crystals, Langmuir-Blodgett (LB) films, self-assembled films, poled polymers [1, 2, 8, 9], zeolites [12], and nanofibers [13].

At present, several organic systems (molecular as well macroscopic) with sufficiently high nonlinearities have been developed. The focus of the research in this area seems to be shifting to the optimization of a variety of other parameters, i.e., thermal and chemical stability and optical loss. Also, new approaches to design efficient nonlinear optical materials have lately emerged [7, 9].

Principles and Origin of Nonlinear Optical (NLO) Effects

In “linear” materials the degree of electron displacement, characterized by the linear

polarizability α , is proportional to the strength of the applied electric field. Nonlinear optical effects arise from the interaction of electromagnetic fields in various dielectric media to produce new fields altered in phase, frequency, amplitude, or other propagation characteristics relative to the incident optical fields with a response that depends nonlinearly on the applied electric field strength. When a beam of light propagates through a material, the electric field associated with the incident beam can provoke small displacements of the electrons within the material. This results in an induced dipole moment (μ_{ind}) which, at low electric field strengths, is linearly proportional to the amplitude of the applied electric field E , the proportionality factor being the first-order polarizability α . However, at high electric field strengths, higher-order terms become significant, and the induced dipole moment can be expanded in a Taylor series in powers of the applied electric fields (Eq. 1):

$$\mu_{\text{ind}} = \alpha E + \beta E^2 + \gamma E^3 + \dots \quad (1)$$

in which β represents the second-order polarizability or first-order hyperpolarizability and γ the third-order polarizability or second-order hyperpolarizability. This description may be expanded to the macroscopic regime of the bulk media with the first-order susceptibility and the second- and third-order nonlinear susceptibility, respectively (Eq. 2):

$$P_{\text{ind}} = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \dots \quad (2)$$

When the polarization of the incident and induced fields is taken in account, the above relations taken on a matrix form with the first and second hyperpolarizabilities (or equivalently the second- and third-order susceptibilities) being three and four rank tensors.

For practical applications, organic second-order NLO materials can be considered to be dipolar molecules organized into non-centrosymmetric lattices. Therefore, high β values are a necessary but not sufficient condition in order to obtain efficient NLO second-order materials [5, 8, 9].

Nonlinear Optical Effects and Their Practical Applications

The main NLO effects associated with linear and nonlinear susceptibilities are [1, 7, 9, 14–16]:

- First-order susceptibility $\chi^{(1)}$: *Refraction* is the change in direction of a light wave due to a change in its phase velocity. This phenomenon is the foundation of most geometric optical effects and has applications in optical fibers and lenses.
- Second-order susceptibility $\chi^{(2)}$:
 - (i) *Optical second harmonic generation (SHG)* is the nonlinear conversion of two photons of frequency ω into a single photon of frequency 2ω ($\omega + \omega \rightarrow 2\omega$) which, in the electric dipole approximation, requires a noncentrosymmetric medium. This effect was first demonstrated by Franken et al. [14] in 1961 and has applications in the frequency doubling of lasers. More recently, SHG-imaging has developed through the last decade as a progressively popular analytical technique especially for high-resolution optical microscopy for biological imaging. In fact nonlinear optical imaging has revolutionized microscopy for the life sciences due to the capacity of this technique to produce high-resolution images from deep inside biological tissues [15].
 - (ii) *Frequency mixing*: an NLO material may be used to add frequencies of two input waves to produce a single wave, whose frequency is their sum: $\omega_1 + \omega_2 \rightarrow \omega_3$ – or difference: $\omega_1 - \omega_2 \rightarrow \omega_3$. This effect has application in the frequency conversion of lasers and various nonlinear spectroscopic techniques.
 - (iii) *Parametric amplification*: an NLO material may transmit two light waves of different frequencies, with one light wave leaving the material amplified at the expense of the other. This effect allows the production coherent light at wavelengths for which no lasers are available

and is frequently used in high-resolution spectroscopy.

- (iv) *Linear electro-optical effect (Pockels effect)* is the change of refractive index of an NLO material which occurs on the application of an electric field, the extent of the change being related to the strength of the field ($\omega + 0 \rightarrow \omega$). This effect has application in waveguides and electro-optical modulators.
- Third-order susceptibility $\chi^{(3)}$:
 - (i) *Kerr effect* is a change in the refractive index of a material in response to an applied electric field. This effect has applications in optical transistors and image processing.
 - (ii) *Third harmonic generation*: light of frequency ω enters the material and leaves with frequency 3ω , ($\omega + \omega + \omega \rightarrow 3\omega$). This effect has applications in optical image processing and scanning microscopy [7].
 - (iii) *Two-photon absorption* is the induced electronic transition provoked by the near simultaneous absorption of two incident photons. This effect was first studied theoretically by Maria Goeppert-Mayer already in the 1931 and is often used in nonlinear microscopy to allow deeper penetration of the incident light, avoid photobleaching, and increase spatial resolution [16].

Nonlinear Optical Materials: Classes, Advantages, and Limitations

The search for novel chromophores for optoelectronics and nonlinear optics (NLO) is one of the main goals of modern materials science and physics. Their practical applications require not only an appropriate design but also the relevant macroscopic properties of newly established materials. The even susceptibilities χ_2 , χ_4 , etc., are only nonzero in materials lacking a center of symmetry. Therefore, the arrangements of the molecules on a macroscopic level are vitally important

to NLO activity. For example, if a crystalline material with a large value of β crystallizes in a centrosymmetric structure, the nonlinear responses of the individual molecules will cancel each other out, and there will be no resultant NLO activity. The same applies to an organic compound with an amorphous structure. If there is no order in the molecule at all, the statistical average of the NLO responses of the molecules will be zero or nearly zero, and again, the material will be not be an active NLO material. Thus to use the strong hyperpolarizabilities often found in organic molecules in a bulk phase, the constituent molecules must be somehow non-centrosymmetrically ordered. The main types of ordered assemblies that have been investigated for use in NLO materials are the following [5, 8–13].

Inorganic

These materials were the first to be studied since the observation by Franken et al. [14] of second harmonic generation in quartz. Several ionic crystals such as potassium dihydrogen phosphate ($\text{KDF}=\text{KH}_2\text{PO}_4$), lithium niobate LiNbO_3 , barium sodium niobate ($\text{Ba}_2\text{NaNb}_5\text{O}_{15}$), and β -barium borate ($\text{BBO}=\text{BaB}_2\text{O}_4$) were developed and are currently used for several optical applications such as frequency converters, electro-optical modulators, and optical switches. The main advantages of inorganic materials are their high stability, high mechanical strength, and high nonlinear optical susceptibilities. However, the growth of these crystals is time consuming (frequently requiring 1–8 weeks) and the crystals tend to be hygroscopic, and expensive, somewhat difficult to integrate into electronic devices and are often limited by the low response speeds.

Coordination and Organometallic Complexes

In the last decade, organometallic and coordination metal complexes have occupied a relevant role in the area of NLO chromophores due to an additional flexibility, when compared to organic

chromophores, owing to the presence of metal-ligand charge transfer (MLCT) transitions usually at relatively low energy and of high intensity, tunable by virtue of the nature, oxidation state, and coordination sphere of the metal center. The main classes of SHG NLO coordination and organometallic complexes include derivatives with monodentate nitrogen donor ligands (amines, stilbazoles, pyridines), chelating ligands (Schiff bases, bipyridines, phenanthrolines, terpyridines), alkenyl, vinylidene and cyclometallated ligands, macrocyclic ligands (porphyrins and phthalocyanines), metallocene derivatives, and chromophores with two metal centers (Fig. 1) [11].

Organic

Dipolar and octopolar organic NLO chromophores (Fig. 2) have several advantages when compared to inorganic materials: (i) ultrafast response times, low dielectric constants, better tailorability and processability, as well as large NLO responses, due to the high electronic polarization of the π electrons of the molecules instead of the distortions of the atoms in the crystal lattice; (ii) easy synthesis and functionalization, allowing the optimization of their structural characteristics leading to the maximization of their NLO properties; and (iii) can be used as monocrystals and films or incorporated into liquid crystals, zeolites, or fibers. On the other hand, they have also several disadvantages such as (i) lower mechanical strength, (ii) lower photochemical stability, (iii) the propensity to acquire defects during crystal growth, and (iv) a somewhat limited working temperature range. Over the past three decades, great progress has been made in the development of new organic donor-acceptor π -conjugated systems [5, 8, 9] being driven by their chemical and thermal stability as well as the ease of synthesis and functionalization which lead to facile optical property tuning. Dipolar push-pull ($D-\pi-A$) organic chromophores are constituted by a π -bridge (aromatic or heteroaromatic) substituted with strong electron donors D (e.g., NR_2 or OR groups) and strong electron acceptor A groups

(e.g., CN, NO_2 , etc.). This $D-\pi-A$ arrangement guarantees efficient intramolecular charge transfer (ICT) between the donor and acceptor groups and generates a dipolar push-pull system featuring low-energy and intense CT absorption (Fig. 2a). The polarizability and the corresponding NLO properties, namely, the SHG of these systems, depend mainly on their chemical structure, particularly the strength of the attached donors and acceptors groups as well as the electronic nature and length of the π -conjugated bridge. However, dipolar chromophores have the tendency for unfavorable aggregation at high concentrations, and it is rare that they undergo noncentrosymmetric crystallization. One way of circumventing these disadvantages is the use of octopolar molecules.

Octopolar NLO chromophores are not so commonly investigated compared to dipolar ones. Nevertheless, their advantage is that they show the same optical transparency as their linear analogues but their second-order response is higher. Due to the fact that they possess zero overall dipole moment, they can often be oriented in the bulk phase in a manner that their molecular polarizability is additive. On the other hand, not possessing a permanent dipole moment invalidates their use in some electro-optical applications. The usual way to design SHG octopolar molecules consists in the synthesis of substituted trigonal or tetrahedral π -conjugated systems that allows an efficient charge transfer from periphery to the center of the molecule (Fig. 2b).

Several one-dimensional charge transfer systems with good SHG properties were developed during the 1980s. Typical examples of such molecules are *p*-nitroaniline (*p*NA) and *N,N*-dimethylaminostilbene (DANS) (Fig. 3); both are still being used as standards to evaluate SHG of other molecules.

Chromophores with other types of conjugated spacers have been also investigated (e.g., substituted benzenes, biphenyls, stilbenes, and azostilbenes). All these systems have a predominantly aromatic ground state and a corresponding charge transfer state that is quinoidal in nature. More recently, the investigation by several groups has led to the development of highly advanced SHG organic chromophores. The results of these

studies suggest that optimal β values could be obtained through two different but complementary methodologies: the optimization of the π -bridge structure for particular donor and acceptor pairs and optimization of donor and acceptor groups for a given π -bridge. Novel highly efficient donor-acceptor pairs have been developed such as alkyl and arylamine electron donors (Fig. 4a) and tricyanofuran-based electron acceptors, for example, 2-dicyanomethylene-3-cyano-4,5,5-trimethyl-2,5-dihydrofuran (TCF1), 2-dicyanomethylene-3-cyano-4,5-dimethyl-5-trifluoromethyl-2,5-dihydrofuran (TCF4), and the tricyanopyrroline (TCP) electron acceptor (Fig. 4b). This arrangement of donor-acceptor pairs combines high chemical, thermal, and photostability [5, 8, 9]. In recent years the enhancement of β values by using ever stronger electron donor or acceptor groups has tended to reach its limit. A versatile methodology to overcome this problem was the

optimization of the π -bridge. Therefore, several experimental and theoretical studies have confirmed that substitution of the benzene ring of a chromophore bridge with easily delocalizable heterocycles (e.g., thiophene, pyrrole, furan, and thiazole) (Fig. 4c) results in improved molecular hyperpolarizability of push-pull systems. Due to their electronic nature and low aromaticity, they can act efficiently as π -bridges as well as auxiliary donors (electron-rich heterocycles: thiophene, pyrrole, furan) or as auxiliary acceptors (electron-deficient heterocycles: thiazole, oxazole, imidazole). In fact, the increase or decrease of the molecular nonlinear activity of these heteroaromatic systems depends not only on the electronic nature of the aromatic rings but also on the location of these heterocycles in the system. Additionally, these heterocyclic systems are also thermally and photochemically stable [8, 9, 17–20].

general TCF and TCP classes, and (c) heterocyclic compounds as π -bridges/auxiliary donor or auxiliary acceptor groups [8]

Colorant, Nonlinear Optical, Fig. 5 Structures of twisted intramolecular charge transfer molecular (TICT) chromophores [9]

Concurrently, multidimensional charge transfer (e.g., X-shaped and higher-order symmetry) and twisted intramolecular charge transfer (TICT) chromophores (Fig. 5) have been explored as alternative approaches to improve hyperpolarizability [9].

The easiest method to impose order on the molecules of a compound is to assemble them into a crystalline matrix. Crystals have several advantages such as their high optical quality and high laser damage thresholds. On the other hand, they have several serious drawbacks; a major one is the fact that most of the promising molecules

have significant ground state dipole moments, which tend to make them crystallize centrosymmetrically. For example, 4-nitroaniline (*p*NA) packs centrosymmetrically and exhibits no appreciable SHG in crystalline form, while the analogous 2-methyl-4-nitroaniline (MNA) packs in an almost perfect head-to-tail arrangement and has a large χ_2 value. There are some examples of noncentrosymmetric small molecules such as derivatives of nitroanilines and nitropyridines or enantiomers of an optically active component. For example, MMONS

Colorant, Nonlinear Optical, Fig. 6 Structure of selected organic NLO crystals [1, 4, 5, 9]

(3-methyl-4-methoxy-4'-nitrostilbene) has a very high powder SHG value (1,250 times that of urea) and POM (3-methyl-4-nitropyridine-*N*-oxide) is the only commercially available organic crystal for SHG, other than urea (Fig. 6).

Polymeric

Oriented Guest-Host Polymers

Second-order NLO applications that require crystalline materials limit the scope of molecule types that can be employed to those that crystallize in acentric space groups. To achieve good device functionality, the NLO chromophore must simultaneously possess high microscopic molecular nonlinearity, good thermal stability, good photostability, low optical absorption, and weak intermolecular electrostatic interactions in a given host matrix. Polymeric materials are attractive because they are compatible with manufacturing methods practiced in industry and can provide durability, environmental protection, and packing advantages not provided by crystalline materials.

Nonlinear optical chromophores can be incorporated into a macroscopic polymeric environment in a variety of ways. Probably the most important and most widely used is the incorporation of dipolar chromophores into a polymer host. In this approach, the active species (the guest) is dissolved in a polymeric host, which is processed to give a thin film. At this stage the molecular dipoles are randomly orientated with respect to each other. The polymer is heated above its glass transition temperature (T_g) allowing the guest molecules to become freely mobile. A strong external electric field is then applied, aligning the dipoles along one direction. With the field still applied, the polymer is cooled below its T_g again, freezing the alignment of the NLO molecules. This approach is successful in obtaining highly oriented NLO materials showing large bulk susceptibilities. The main disadvantages are (i) gradual disordering of the dipoles, (ii) limited solubility of the active species in the host polymer which limits the attainable NLO activity, and (iii) dielectrically induced breakdown of the NLO species during poling. The advantages of the poled polymer approach are the relative ease of thin film

Colorant, Nonlinear Optical, Fig. 7 Structure of selected organic chromophores used in guest-host polymers [8, 9]

making by spin coating and its compatibility with existing semiconductor technology. Figure 7 shows the structures of some examples of organic chromophores used as guests in guest-hosts polymeric systems.

Oriented Side-Chain and Main-Chain Polymers

Nonlinear optical chromophores can be also incorporated into a polymer by covalently attaching the chromophores to a polymeric backbone as part of the side chain (side-chain polymers) or by incorporation of the chromophores into the backbone of the polymer (main-chain polymers).

Langmuir-Blodgett Films

Another approach to organize molecules has been to incorporate organic NLO chromophores into noncentrosymmetric Langmuir-Blodgett films. The Langmuir-Blodgett film technique is used to build up ordered assemblies of molecules onto a substrate from a floating monolayer on a liquid, usually water. The molecule must be amphiphilic, that is, hydrophilic at one end and hydrophobic at the other, so that the molecules in the monolayer at

the water's surface have uniform orientation. This approach offers the advantage of much greater chromophore alignment and chromophore density. However, these films often have poor optical quality and poor temporal stability and are often very fragile.

Zeolites

Zeolites and the related mesoporous materials have been also tested as the hosts for aligned inclusion of dipolar organic NLO dyes as a possible means to overcome the problems arising from the use of polymer matrices. The first dyes tested were *p*-nitroaniline (*p*NA), 2-methyl-4-nitroaniline (MNA), and 2-amino-4-nitropyridine which have low molecular second-order hyperpolarizability values, and the zeolites have been mostly limited to powders that bear limited practical applicability. More recently hemicyanine dyes (Fig. 8) exhibiting higher β values and a high degree of uniform orientation were introduced into transparent zeolite films with uniformly oriented channels. These second-order NLO dye-incorporating films have shown higher thermal and mechanical stability without any notable loss of activity with time. They have a

strong potential to be practically applied in industry [12].

Nanofibers

Very recently, nanofibers of poly(L-lactic) acid (PLLA) produced by the electrospinning technique, in which donor-acceptor organic compounds such as 2-methyl-4-nitroaniline, urea, and β -glycine were imbedded, exhibit a permanent nonvanishing quadratic nonlinear susceptibility. The nonlinear optical properties displayed indicate that a noncentrosymmetric polar state was achieved and maintained a long time, allowing the use of otherwise centrosymmetric organic materials. Moreover, it was proved that the SHG efficiency of these fibers strongly depends on the diameter of the nanofibers and can be increased up to an order of magnitude by controlling the electrospinning processing parameters [13].

As most of the donor-acceptor organic molecules with large hyperpolarizabilities tend to crystallize in centrosymmetric structures which invalidate their use in quadratic nonlinear optical applications, the inclusion of these molecules in electrospun nanofibers may provide a means of overcoming this limitation for any donor-acceptor organic molecules with delocalized π electrons. The results of this work could have a direct impact on the design of novel nanodevices for a variety of nanophotonic applications (e.g., electro-optical transducers, pyroelectric sensors, optical frequency converters).

Experimental Methods for the Determination of Second-Order Nonlinear Effects

The second-order polarizability β and the second-order susceptibility $\chi^{(2)}$ are two parameters

Colorant, Nonlinear Optical,

Fig. 10 Experimental setup for the determination of SHG through hyper-Rayleigh scattering technique (Nonlinear Optics Laboratory of the Physics Center at the University of Minho) [19, 20]

indicative of a second-order response [5, 9]. The first is a molecular parameter and is usually measured in solution, whereas the latter is typically measured by second harmonic generation from the solid state. Several experimental techniques can be used in order to study these parameters in solution or in solid state: solvatochromic method, Kurtz powder technique, Maker fringes, electric field-induced second harmonic (EFISH) technique, and the hyper-Rayleigh scattering (HRS) technique (Figs. 9 and 10). In solution, the two major techniques that are presently used are EFISH and HRS.

Future and Perspectives

From the proceeding description, it is clear that the molecular design of molecules with strong nonlinear optical responses has reached a high level of sophistication. Important advances are likely to come from breakthroughs in methods that are able to make use of these strong individual molecular responses by incorporating in restricted environments that break their tendency to aggregate in centrosymmetric forms. The future of organic nonlinear optical materials is undoubtedly a bright one.

Colorant, Photochromic

Andrew Towns

Lambson Ltd., Wetherby, West Yorkshire, UK

Definition

The defining characteristic of photochromic colorants is that they change color reversibly in response to variations in the intensity of particular wavelengths of light to which they are exposed. Industry has been successfully exploiting such dyes for more than a quarter of a century, manufacturing millions of dollars' worth each year [4, 18]. The majority is consumed in the production of ophthalmic lenses that darken reversibly when exposed to strong sunshine. Photochromism continues to attract the interest of both industrial and academic researchers, who are looking to harness photochromic colorants in fields like optoelectronics and nanotechnology.

Photochromism

The widely accepted definition of photochromism is that of a reversible color change induced in a compound driven in one or both directions by the action of electromagnetic radiation [8, 9]. Photochromic systems are classified as either “P-type” or “T-type.” The former kind can be switched in each direction with different wavelengths of light. P-type systems change color when irradiated with a specific wavelength range and then remain in this state after removal of the stimulus. It is only when they are subjected to light of a different set of wavelengths that they return to their original color. In contrast, T-type behavior is exhibited if light is able to drive the change in just one direction. T-type systems will fade back to their original state, through a thermal back-reaction, when they are no longer exposed to the light source. Reversibility of response is a key aspect in both types of photochromism: light-sensitive materials that undergo changes of an irreversible nature cannot be described as photochromic.

Real-world colorants do not always match the strict definitions of the two kinds of behavior, as discussed further below. Nevertheless, most are readily categorized. Photochromic compounds of either type are available commercially. While T-type dyes are far more important industrially, there is much interest in P-type materials. Figure 1 very generally captures the behavior of both kinds.

The first major application of photochromism was commercialized in the mid-1960s: glass ophthalmic lenses that relied on inorganic halide crystals. These systems have been superseded during the past three decades by organic materials in the form of plastic lenses incorporating T-type dyes [7, 17]. Such colorants are colorless – so to describe them as dyes might initially seem odd! – but they become colored when irradiated with sunlight and fade back thermally to colorless in low levels of light. Developing an economic technology with commercially acceptable durability and performance did not prove easy because photochromic colorants are less robust than conventional dyes and orders of magnitude more expensive. Light-responsive organic compounds that can be switched from one color to another are well known, but because photochromic lens manufacture remains the dominant application, the most industrially important dyes are those which exhibit T-type behavior as depicted in Fig. 1 involving colorless to colored transitions. This kind of color change, in which light causes a shift in absorption to longer wavelengths, is known as “positive photochromism.” The term “negative photochromism” does not mean non-photochromic, but instead covers the converse phenomenon of a colored dye becoming colorless

upon irradiation with light, only to return to its original colored state in the dark [1, 3].

T-Type Photochromic Colorants

There are many examples of organic compounds that change color upon irradiation with light and revert to their original state following removal of the illuminant [5, 6, 8]. The photochromism is T-type because the back reaction is driven thermally, although for commercial photochromic classes visible light may also contribute. The rate of thermal fading is often expressed as “half-life” which is the time taken for absorbance to halve once the activating light has been removed. For ophthalmic utility, a short half-life is desirable to stop vision being impaired when there is a sudden drop in light intensity [17]. However, a commercially interesting colorant for lens production must satisfy numerous other requirements:

- Weak visible absorption when unactivated so residual color is low
- Quick response to an increase in illumination
- Have a strongly absorbing activated state, because even when irradiated with light of high intensity, only a relatively small proportion of colorant will exist in this form
- Show a good compromise between depth of activated color and rate of fade to ensure both are acceptable as the properties of high intensity and short half-life tend to be mutually exclusive
- Produce satisfactory performance over 2 years by having reasonably lightfast colored and colorless forms which respond well to photostabilizers

Colorant, Photochromic, Fig. 1 General behavior of most commercial T-type and P-type photochromic colorants

- Resist the tendency to “fatigue,” whereby during activation, a proportion of the dye is undesirably and irreversibly converted to non-photochromic molecules, leading to gradual weakening of color upon repeated activation
- Color up in a manner that is not greatly affected by the temperature of its environment
- Exhibit sufficient solubility in lens media to give solutions rather than dispersions because commercial T-type classes do not exhibit useful photochromism in solid form

All commercial T-type dye classes undergo the same kind of molecular transformation, photoisomerization, as illustrated by an example of the well-studied spiropyran family in Fig. 2 [5, 9]. The geometries of commercial T-type colorants change substantially when switching between colorless and colored states. Consequently, the medium in which a dye is dissolved can markedly influence its photochromism. Non-polar solvents typically provide a favorable environment for photoisomerization, whereas, as discussed below, polymers can inhibit interconversion.

The wavelengths of light that effect the forward conversion shown in Fig. 2 are normally within the UVA region (315–400 nm), but blue light can also play a role for some commercial spiro-derivatives. Absorption causes rearrangement of the bonding between the atoms within a colorless or weakly colored molecule to create structures that confer intense color. The colorless form consists of a ring-closed structure, which is made up of two halves that are perpendicular to each other and joined by a spiro carbon atom. The π -systems of these moieties are small and

essentially isolated from each other, hence the lack of absorption in the visible region. However, absorption of energy in the form of UV light can lead to ring-opening as a result of the bond between the spiro carbon atom and its adjacent oxygen atom breaking. Molecular twisting and bending via intermediates then ensues giving planar species with extended conjugated π -systems whose absorption moves into the visible, generating color. Low light levels result in ring-closure back to the colorless form because thermal fading dominates.

Different forms of the dyes exist in a dynamic equilibrium: at a given moment, molecules are isomerizing between colored and colorless species, whose concentrations are determined by the intensity of incident light. As the flux of UV to which the dye is exposed increases, the proportion of dye that is in its colored state grows through promotion of ring-opening relative to ring-closure. Removal of the light source leads to the concentration of the colorless ring-closed form rising, which is observed as fading. When the intensity of illumination is held constant, the isomer concentrations will settle down into what is known as a “photostationary state,” where depth of color does not change. These proportions are dependent on the dye, the nature of the illumination and the medium. Because the photostationary state is a dynamic equilibrium, dye molecules will continue to swap between colorless and colored isomeric forms even after it has been attained.

Since a significant proportion of sunlight is made up of radiation in the UV, it is capable of causing pronounced photochromism. In contrast, most commercial T-type dyes do not respond well to artificial light sources, such as tungsten filament

Colorant, Photochromic, Fig. 2 Photochromism of typical example of the spiropyran class

Colorant, Photochromic, Fig. 3 Some photochromic oxazines of commercial importance

bulbs, because the proportion of their UV output is low.

Several classes of T-type compounds have been extensively investigated (e.g., anils, perimidinespirocyclohexadienones, spirodihydroindolizines, etc.) [5, 6], but few have attained commercial significance. The three families of dye that have had the greatest industrial importance will be discussed next.

Spiropyrans

This class was intensively studied during the 1950s through to the 1970s because many of its members are readily synthesized and photochrome to deep colors, typically violets and blues, that fade at useful rates [5]. However, their generally poor photostability prevented successful commercial exploitation. Nevertheless, the spiropyran unit continues to be of interest in research where light stability is not of critical importance, for example, in the fields of biochemistry and materials science [15].

Spirooxazines

Although spirooxazines [5, 16] are similar in structure to spiropyrans, the former are much less prone to fatigue [6, 9]. As a result, they have become well established since they were employed in the production of the first commercial plastic photochromic lenses in the early 1980s [17].

Dyes derived from the indolinospirooxazine [2,1-b][1,4]oxazine **1**, indolinospirooxazine [1,2-b][1,4]

oxazine **2**, and indolinospiropyridobenzoxazine **3** classes have all have enjoyed extensive use in ophthalmic lens manufacture (see Fig. 3) [4, 18]. The simplest examples give relatively fast-fading blue photocoloration, but small adjustments to structure furnish dyes with useful intensities and half-lives. For example, placing bulky alkyl groups on the indoline nitrogen (substituent R in Fig. 3) slows down fading and increases strength. Manipulation of color is also possible with appropriate design making bluish-red through to turquoise dyes accessible commercially. Dyes **3** were successfully utilized as the blue components of a photochromic colorant mixture in the production of the first true grey photochromic lenses in the early 1990s.

Naphthopyrans

The naphthopyran class [5, 12] is the most commercially important variety of photochromic dye [4, 18]. All the major manufacturers of polymer-based photochromic lenses make use of naphthopyrans in their formulations. Their chemistry facilitates the economical production of a palette of dyes that not only spans the visible spectrum from yellows through to oranges, reds, purples, and blues, but also features more neutral colors such as olive, brown and grey. This family offers considerable scope for fine-tuning of photochromic properties because many convenient modifications to structure are possible. However, careful design is needed since substituent choice usually

Colorant, Photochromic, Fig. 4 Some photochromic naphthopyrans of commercial importance

affects both conversion kinetics and color. The stability of such dyes is generally as good as any other class, while their photochromism tends to be more independent of temperature than that of spirooxazines. The above advantages have led to naphthopyrans becoming the most commercially important type of photochromic colorant in the form of two subclasses: *3H*-naphtho[2,1-*b*]pyrans **4** and *2H*-naphtho[1,2-*b*]pyrans **5** (see Fig. 4).

Another reason for the significance of naphthopyrans is that they simplify the development of colorant recipes for lenses of the most commercially important shades, which are grey and brown [4, 18]. Incorporation of appropriate structural features into **5** produces relatively dull, neutral dyes, enabling use of fewer colorants in a mixture. Of particular industrial usefulness are “indeno-fused” dyes of general structure **6**, whose photocoloration features more than one broad absorption band in their visible spectra, furnishing murky tertiary olive, dull blue, purplish and even grey shades [18]. Given that the components of a recipe must activate, fade, and fatigue at the same rate, use of such dyes as their principal elements constitutes a great advantage to the formulator.

Applications of T-Type Dyes

While the properties of photochromic colorants have been put to purely aesthetic use in artwork, T-type dyes have also been exploited as functional materials, for example, in security printing where light-responsive marks are used as indicators of authenticity. The main outlet for photochromic dyes, lenses for spectacles, falls between these two extremes: variable transmittance is a key function in regulating light intensity reaching the eye, yet color is also an important consideration for style, comfort, and visual acuity. Although T-type colorants have been investigated for many applications, success in developing marketable products has been limited by the challenges that their usage presents. They are not as robust as conventional dyes and pigments, rendering certain methods of application unsuitable. In order to get strong, durable photocoloration, care must also be taken to provide T-type dyes with the right environment in which to operate. It must be conducive to the changes in molecular geometry associated with photochromism and not lead to rapid degradation of dye during and/or following application. These considerations will be illustrated for polymers and surface coatings, which are the two most common media for photochromic dyes.

Arresting photochromic effects can be produced by incorporation of dyes into thermoplastics. However, the chemical and physical properties of the polymer (as well as the dye) exert a large influence on the kinetics and resilience of the photochromism. For example, spirooxazines and naphthopyrans work well when used in mass coloration of polymers that have relatively low glass transition temperatures with flexible chains, such as polyethylene and polypropylene, giving striking color changes at inclusion levels of 0.3%w/w and less. However, rigid, crystalline materials restrict the necessary conformational changes for photoisomerization, severely inhibiting photochromism. Dyes can tolerate brief exposure to the high temperatures experienced in injection molding or extrusion, but certain polymers, such as polyamides, require processing at elevated temperatures that strongly degrade colorants, leading to discoloration and a lack of observable photochromism. Even when suitable polymers are employed, additives are often needed to enhance dye photostability so that the effect has a commercially acceptable lifetime. Loss of photochromism in industrial systems is related to the cumulative amount of incident UV radiation rather than the number of times that the material is switched between colorless and colored states. Consequently, UV absorbers can usefully shield dyes from excessive radiation if they do not strongly absorb the UV wavelengths which activate the dyes. Other additives include hindered amine light stabilizers that scavenge light-generated free radicals, which would otherwise attack colorants, and triplet state quenchers that inhibit photochemical reactions other than the desired one of photoisomerization.

Application to polymers need not involve monomolecular dissolution in the polymer itself. Photochromic dyes can also be used in microencapsulated solvent droplets of typically 1–10 μm in diameter. In this form, the dye solution is encased in polymer shells, producing a photochromic composite that can be dispersed like a pigment. The advantage of this material is that its photochromism is much more independent of the medium. The properties are that of the dye

dissolved in the solvent and do not tend to be influenced by the polymer in which the microcapsules are dispersed. In this way photochromic effects can be produced in substrates using the microencapsulate that would not be possible using dye alone. Disadvantages of this technique are the relatively high loadings of pigment required and the potential for microcapsules to be physically damaged during application. An alternative approach to obtaining photochromism in inhospitable polymers (as well as potentially improving the robustness and responsiveness of the effect) is to attach oligomeric fragments to dyes, for example, poly(siloxane) and poly(ether) chains [18]. These pendant oligomers are thought to provide a favorable microenvironment for the photoactive part of the colorant. All of these methodologies have been commercialized for coloration of polymers. Photochromic materials are found in products as diverse as toys, fashion accessories, fishing line, and motorcycle helmet visors [4].

T-type colorants have also been used for applications ranging from security printing to cosmetics, in the form of photochromic inks and other surface coatings. Commercial dyes work well in non-polar solvents such as toluene. When dissolved at a suitable concentration, solubility, and photochromic behavior tend to be good, enabling the formulation of solvent-based inks and varnishes. Aqueous media require an alternative approach since such dyes are not water-soluble but must be in solution to exhibit photochromism. One way is to disperse microencapsulated dyes into water-based systems using commercially available powders or aqueous slurries. Alternatively, micronized particles of an appropriate polymer into which photochromic dye has been incorporated can be employed. It is also possible to formulate inks for a variety of printing techniques, provided care is taken to ensure that dye is not damaged during formulation or application. Additives may be needed to improve light fastness. Even following optimization, photostability can be problematic. This is also true of photochromic textiles: the most effective method of applying dye to fabric is screen-printing microencapsulated colorant

because typical fibers, such as polyester, inhibit photochromism while conventional techniques, for example exhaustion dyeing, tend to damage typical commercial dyes. Photochromic detail can be added to garments through the use of polypropylene thread that has been melt-spun with dye [4].

The general lack of robustness of photochromic dyes compared to conventional colorants has prevented their use in particularly demanding applications. One example is light-responsive glass for architectural windows. Lifetimes in excess of 10 years are required but such a demand cannot be met by existing dye technology.

T-type colorants are also not suited to potentially important uses which require controlled switching between one or more states (colored and/or colorless) on demand: for these applications, P-type dyes are needed.

P-Type Photochromic Colorants

A significant amount of effort, in both academia and industry, has been invested in P-type colorants over the past three decades because of their potential as molecular switches [11]. Such compounds are converted from one state to another by irradiation with light, remaining so until switched back by other wavelengths. This behavior is of great interest in high technology sectors, but while much time and money has been spent on developing P-type applications, these endeavors have yet to bear commercial fruit.

The classes that have been studied most in this connection are discussed next.

Diarylethenes

Of P-type families of colorants, this class [5, 11, 13] has arguably been subjected to the most intense scrutiny. In contrast to commercial T-type dyes, their photochromism relies upon UV light causing ring-closure rather than ring-opening (see Fig. 5).

With appropriate structural design, the colored cyclized material is essentially thermally stable (owing to a negligibly small reaction rate for thermal reversion) so that the reverse reaction does not occur in the dark. Instead, ring-opening requires the absorption of longer wavelengths of visible light than those that cause activation. Consequently, unlike pyran- and oxazine-derived colorants, diarylethenes do not fade spontaneously once the illumination is removed. A further contrast is that, whereas commercial T-type compounds must be in solution to produce useful photochromism, diarylethenes give photochromic responses in solid form (follow this [link](#) for a video). The derivatives that have attracted the greatest attention are members of the dithienylhexafluorocyclopentene subclass **7**. A few of them are available on the open market in small quantities. Activated colors can be varied widely by modification of their structure: collectively, members of this class cover most of the visible spectrum. By linking together different diarylethene skeletons, photochromic molecules have been created that can even be selectively

diarylethenes using the

X, Y = H, alkyl, fused (het)aryl, etc.

dithienylhexafluorocyclopentene class (7) as an example

switched between more than one different colored state.

Fulgides

Derivatives drawn from this class [2, 5, 9] have been observed to exhibit various kinds of chromic behavior of which P-type photochromism is one. Like diarylethenes, generation of color involves a ring-closure reaction upon exposure to UV radiation either in solution or as a solid. By judicious choice of structure, transitions from nearly colorless to yellow, to red, and even into the infrared region are possible. Fading is caused by absorption of certain wavelengths of visible light. An example of this class that has been commercially available is shown in Fig. 6. When activated, dye **8** changes color from pale yellow to red.

Applications of P-Type Dyes

Fulgides have been used in conventional coloration areas such as textiles and printing inks [2]. However, the greatest interest in P-type photochromic systems stems from their potential use as functional colorants within the fields of optoelectronics, data storage, nanotechnology, and medicine [10, 11, 13, 20]. In these contexts, diarylethenes have been the most intensely studied family as they offer a wide scope for the design of molecules whose optical properties can be switched in a controlled manner between persistent states. Much effort has been expended on trying to exploit this behavior, for example, in

developing components for all-optical circuitry, such as switches and logic gates. Optical equivalents to electrical components, perhaps reliant on P-type colorants, are needed if the technology is to replace slower, more power-hungry conventional electronics. Molecules that can be switched optically are also being studied in the field of information technology because in theory they could furnish memory systems with much greater data storage densities than those of current commercial devices.

Another avenue of research for P-type colorants is nanotechnology because of their solid phase photochromism. For example, crystals of dihetarylethenes undergo changes in shape, as well as color, as a consequence of molecular geometry altering during photochromic transitions (follow this [link](#) for a video). Such alteration in particle dimensions could form the basis for light-driven actuators in nanomachinery.

One of the oldest known photochromic systems, azobenzene, has come under increased scrutiny as a means of creating materials with light sensitive properties [21]. Azobenzene has an element of both T- and P-type character as shown in Fig. 7.

The rate of thermal back reaction can be slowed by structural modification, creating materials with strong P-type behavior where *trans* to *cis* photoisomerization occurs with one range of wavelengths and *cis* to *trans* with another set [21]. These transformations have been explored

Colorant, Photochromic,
Fig. 6 Photoisomerization of fulgides as exemplified by furylfulgide **8**

Colorant, Photochromic,
Fig. 7 Photochromism of azobenzene

for use in optical switching and data storage. The geometry change associated with photoisomerization attracts much interest as a means of creating polymeric materials that undergo reversible photomechanical deformation [14, 19]. Films which contract upon exposure to UV light and then expand when irradiated with visible light have been used to demonstrate the concept of light-driven motors (follow this [link](#) for a video).

The considerable research effort dedicated to exploiting new and old P-type photochromic systems includes Nobel Prize winning work [10]. Nevertheless, T-type photochromism remains the most commercially important phenomenon, primarily in the form of naphthopyran colorants. If one of the nascent applications of P-type dyes does however become an industrial reality, then usage of such materials would likely grow to dwarf the current volume of photochromic dyes consumed.

Colorant, Textile

Andrew Towns
Lambson Ltd, Wetherby, West Yorkshire, UK

Definition

Textile colorants impart color to a textile material, usually with a high degree of permanency, as a result of their chemical binding or physical entrapment within or around the textile material. The

textile material may be in one of several forms such as fiber, yarn, fabric, garment, etc. Textile colorants are supplied in both solid and liquid forms, for example, as powders, granules, solutions, or dispersions. In certain instances, precursors are applied to textile materials to generate the colorant in situ within the textile.

Textile Dyes and Pigments

Both dyes and pigments are used in the coloration of textiles [1, 2]. The former substances are present in solution at some point during their application, whereas the latter colorants remain insoluble within any vehicle in which they are applied as well as within the textile material itself [3]. Pigments must therefore either be incorporated into textile fibers during their construction (e.g. mass coloration of a polymer followed by its melt extrusion into fibers) or be printed onto a fabric as part of a formulation that contains a binder so that the colorant is physically held to the surface of the textile in a coating. Textile dyes are usually applied from solution although certain types may be present initially as a dispersion or applied from the vapor phase. The mechanism by which dyes remain within a textile depends on the particular colorant type. Retention may rely on intermolecular forces operating between dye and fiber following adsorption onto and/or dissolution within the polymer, formation of covalent bonds between the dye and the fiber, or entrapment of colorant particles within the textile by deposition of an insoluble form of the dye.

Natural Textile Colorants

Prior to the synthesis of picric acid in the eighteenth century as a yellow dye for silk, all textile colorants were obtained directly from natural sources, such as plants, insects, and shellfish [1, 4]. These natural colorants began to be superseded by synthetic dyes and pigments in Europe during the second half of the nineteenth century. These early artificial products enabled dyers to create a wider gamut of shades and more brilliant hues

than had hitherto been possible. While there has been a revival of interest recently in natural textile colorants driven by perceptions of renewable sourcing and low environmental impact, they are less suited to high-volume industrial use for a variety of reasons. For example, they offer only a limited gamut and generally display moderate levels of fastness at best. In addition, natural dyes often require the use of a fixative, known as a *mordant*, to achieve satisfactory permanency; traditional metallic mordants are environmentally unfriendly. Textile dyes that were originally obtained from natural sources, such as Indigo, are more efficiently obtained by chemical synthesis [1, 5]. Such substantial areas of land are needed to cultivate crops from which to harvest plant-based colorants that it would not be possible to meet the current global demand for textile dyes. Consequently, while textile coloration with natural dyes is practiced commercially, it remains a low-volume activity at the high value end of the market.

Synthetic Textile Colorants

The vast majority of textile colorants are synthesized chemically on an industrial scale [5, 6]. Over a million tons are produced globally each year. Tens of thousands of colorants have been marketed since the first commercially successful synthetic textile dye, *Mauveine*, was manufactured in the late 1850s [1, 7]. The financial rewards from this particular colorant and its contemporaries spurred on much endeavor into making synthetic dyes. The genesis of the modern chemical industry, which dwarfs the colorant sector and now manufactures products as diverse as plastics, pharmaceuticals, and drugs, lies in the attempts of mid-nineteenth century chemists to prepare textile dyes and other colorants. These efforts initially involved a trial-and-error approach since little was known about molecular structure and dyes often reached the market as mixtures of different compounds with their inventors having little idea of their composition. However, a more systematic approach to textile colorant research, principally led by the German

dye industry, resulted in a better understanding of both chemistry and color–structure relationships. At the beginning of the twentieth century, Germany manufactured 85% of the world’s synthetic dyes with 10% being produced in Britain, France and Switzerland. Over a century later, manufacture is concentrated in Asia, particularly China and India, although some of the biggest suppliers remain headquartered in Europe. This shift was originally driven by the lower cost bases of eastern producers relative to those of existing manufacturing sites in Europe and North America. Contributors to the disparity included reduced capital costs, cheaper labor, and less stringent environmental constraints than were prevalent in the West at the time. The global market for textile colorants is worth several billion dollars [3]. The textile industry is the largest consumer of dyes and organic pigments. Some of the biggest-selling textile dyes are truly commodities, being produced in volumes of over one thousand tons each year for supply at just a few dollars per kilogram or even less.

Nomenclature and Composition of Commercial Textile Colorants

Traditionally, the trade names which manufacturers give to colorants are typically comprised of three parts [5]. The first element is a brand name, often incorporating elements of the producer’s name, the type of colorant, and/or its intended use. The next part indicates general color, occasionally with modifiers to highlight shade or application characteristics to which the manufacturer wants to draw attention. The last part of the name is made up of a code of letters and numbers for further differentiation of the colorant from others – these may be related to color, application properties, as well as strength. For example, the now-defunct manufacturer, *Holliday Dyes and Chemicals*, marketed the dye *Polycron Yellow C-5G 200%*. “Polycron” was the name shared by the company’s disperse dyes developed solely for the coloration of polyester; “C” denoted the disperse dye application category into which this colorant fell; “5G” indicated that it had a

relatively greenish hue; the suffix “200%” signified that its tinctorial strength was double that of the market norm (“100%”), i.e. twice the amount of active dye was present per unit mass of colorant. Many other companies employ this system of nomenclature for their colorants. However, reliance on commercial names alone will not necessarily enable informed colorant selection (i.e. which colorant to use for a particular substrate and application technique), nor show which textile colorants in the market are equivalent. Fortunately, many manufacturers link their products to the *Colour Index* (CI) generic naming system which assists users in making sense of the vast array of textile colorants that are commercially available. (Note the British English spelling of color in the title as the nomenclature scheme was originated in the UK.) For instance, Polycron Yellow C-5G 200% has a CI Generic Name assigned to it, CI Disperse Yellow 119, thereby allowing users to identify equivalent products. While colorants with the same CI Generic Name ought to contain the same main colored compound, they may not be exactly equivalent. Variations in impurity content, whether inadvertent or through deliberate inclusion of shading components, may affect color or other application properties. Differences in physical form can affect performance. Members of several types of dye class typically include substantial quantities of additives, present as processing aids, such as dispersing agents or buffers to stabilize pH. Another source of variation is the presence of a diluent, for example salt or dextrin, which is added to standardize certain dye types to a desired tinctorial strength. A further potential complication is that some textile colorants do not have a CI Generic Name, either because they are mixtures of colored components as is often the case with navy and black dyes, or simply because one has not been disclosed or assigned.

Textile Colorant Structure

The constitution of commercial dyes and pigments used for textile coloration can be described as lean: each part of a colorant molecule has one or

more purposes as will be illustrated in some of the following sections. These functions may be related to adjustment of color (e.g., hue, intensity, brightness), physical character (e.g., solubility, crystal structure, volatility), dyeing behavior (e.g., substantivity, leveling), fastness (e.g., light, heat, moisture) and so on, although there will be occasions when substituents are present merely for convenience or cost [7]. Often, dye design involves an element of compromise as certain properties will have a degree of mutual exclusivity, e.g. rapid dyeing and good leveling behavior at the expense of high wash fastness. The most general structural classification centers on the key molecular features of a colorant that gives rise to its color. Azo derivatives are the largest such class of textile colorants, although there are many others of significance.

Azo Textile Colorants

This class is defined by the presence within the colorant molecule of an arylazo group of general structure ($\text{Ar}-\text{N}=\text{N}-\text{X}$) where X is most commonly another aryl ring [5–8]. In many industrial colorants, the azo function exists exclusively in a more energetically stable hydrazone form ($\text{Ar}-\text{NH}-\text{N}=\text{X}$) instead [1]. Coverage of the whole visible spectrum is possible using

commercial dyes containing just a single azo or hydrazone bridge, although many important textile dyes contain two or more such groups [1, 5, 7, 8]. Azo colorants make up around half the number of textile dyes and pigments available. This dominance lies in their economy, robustness, and versatility. Not only are they relatively inexpensive to manufacture, but generally azo derivatives also have good tinctorial strength and so tend to be economical compared to other colorant types. The class has also offered manufacturers much scope to adjust structure, enabling them to readily modify properties including shade, solubility, dyeing behavior, as well as fastness [7]. Figure 1 illustrates how structure can be divided into fragments with different purposes using the highest volume navy blue dye for polyester (CI Disperse Blue 79) as an example.

Carbonyl Textile Colorants

The color and application properties of this group of dyes and pigments are dependent on carbonyl functions ($>\text{C}=\text{O}$) [1, 5, 7, 8]. A major subclass is based on 9,10-anthraquinone, because it is a source of red to blue, as well as green, dyes of high brightness and fastness. However, economic considerations restrict their use - they are generally more expensive to manufacture than azo

Colorant, Textile, Fig. 1 Structural features of CI Disperse Blue 79

Colorant, Textile,
Fig. 2 Structural features
 of CI Acid Violet 43

derivatives, while their relatively low tinctorial strength compared to other classes means that more dye must be used to achieve a particular depth. An example of a commercial anthraquinone dye is shown in Fig. 2.

This group also encompasses one of the oldest types of textile dyes, *indigoid*, and one of the newest, *benzodifuranone*. The latter is shown in Fig. 3 and is a commercially useful source of intense bright red dyes [5].

Other Textile Colorant Structural Types

There are numerous other structural classes of textile dyes [1, 5, 7, 8] and pigments [6, 7], each occupying its own application niches. A few examples are presented in Fig. 3. The *triarylmethine* class dates all the way back to the 1850s, although the importance of such purple, blue and green dyes has diminished with the development of alternative chemical types of superior fastness. The same is true of yellow to red fluorescent *xanthene* dyes as textile colorants. However, the *phthalocyanine* class remains as much prized as ever since its commercialization in the first half of the twentieth century. This colorant type furnishes robust and tinctorially strong bright blue to green dyes and pigments with diverse uses in the textile arena, especially when they are in the form of copper complexes [5, 6]. Other classes occupy more specific sectors in terms of color and/or application. For example, *triphenyldioxazines* are exploited as intense bright blue dyes for natural fibers, while *nitrodiophenylamines* are cost-effective yellow colorants of

good photostability for synthetics [5]. Polymethine dyes are a broad class of chromophore of which certain subclasses are employed in textile coloration: two such types, *hemicyanines* and *diazahemicyanines*, are shown in Fig. 3. Both families are useful for intense bright reds, while the latter also supplies blue colorants [5, 8].

Textile Colorant Application Classes

Although knowledge of the molecular structure of a textile colorant is essential for a manufacturer, the user is concerned more with its method of application and performance [3, 9]. Modes of dye and pigment use include mass coloration, exhaustion dyeing, thermofixation, and printing by screen, inkjet or sublimation – each calls for a different mix of behaviors, while commercial demands will dictate economic and quality criteria [10]. A useful way of grouping textile colorants into sets with very broadly similar characteristics in terms of color, usage, fastness and economy is by CI application class. The most important application classes of textile colorant are listed in Table 1 and described in more detail below [1, 2, 5, 7–10].

Acid Dyes

This type of anionic colorant is commonly used to dye and print natural (wool, silk) and synthetic (nylon) polyamides [2, 5, 7–10]. The class is named after the acidic (pH 2–6) dyebaths used for dye application. Lowering pH increases the concentration of cationic ammonium groups

Colorant, Textile, Fig. 3 Some important textile colorant structural types

Colorant, Textile, Table 1 Major textile colorant application classes

Class	Principal textile substrate
Acid	Wool, silk, nylon, modified polyacrylonitrile
Azoic	Cotton and other cellulose, acetates
Basic	Polyacrylonitrile, modified nylon and polyester
Direct	Cotton and other cellulose, polyamide
Disperse	Polyester, acetates, nylon, polyacrylonitrile
Pigment	Cotton, polyester
Reactive	Cotton, wool, silk, nylon
Sulfur	Cotton and other cellulose
Vat	Cotton and other cellulose, polyamide

within these substrates, enhancing their attraction for anionic dyes. While anthraquinone and triarylmethine derivatives are significant for violet, blue and green colorants, azo compounds are by far the most important structural class. A substantial proportion of acid dyes are metal complexes that comprise one or two dye ligands; of particular importance are 1:2 chromium:dye ligand complexes as these furnish dull, deep shades of good wet fastness and high photostability. Dyeing performance and fastness

properties are readily modified by adjusting dye hydrophobicity (see Fig. 4).

Azoic Colorants

These colorants are employed predominantly on cellulosic fibers [8, 10]. They are water-insoluble azo compounds that are synthesized within the textile substrate during the dyeing process from soluble precursors. The colorants generated are physically trapped as solid particles within fiber pores, so dyeings display good fastness to laundering and light. There are numerous variations in technique and materials, but the usual method is to apply a naphthol coupling component followed by a diazo component, which reacts with the coupler to produce a non-ionic colorant. The diazo component is an aromatic amine, which is diazotized as part of the application process, or supplied as stabilized pre-diazotized materials, for example, aryldiazonium tetrafluoroborate salts (i.e., $\text{ArN}_2^+\text{BF}_4^-$). Azoic textile colorants have largely been sidelined industrially owing to the greater convenience and economy of other systems, but are still of commercial interest in the red shade area.

Colorant, Textile,**Fig. 4** Structural features of CI Acid Red 1 and CI Acid Red 138**Colorant, Textile,****Fig. 5** Structural features of CI Basic Yellow 28**Basic Dyes**

Members of this class are used primarily for coloration of polyacrylonitrile, either by exhaustion dyeing or during fiber production [2, 5, 7]. They are often referred to as cationic dyes because their molecular structures feature a positive charge as shown for example in Fig. 5. This charge may be pendant (i.e., localized but isolated from the chromophore) or delocalized, forming part of the chromophore itself [8]. In either case, the dye binds to the substrate by electrostatic interaction. Triarylmethine colorants are significant in the blue and green sectors, while azo and cyanine-type dyes dominate the yellow to violet areas [7]. All can furnish bright intense shades of high wet and light fastness.

Direct Dyes

This class is so named because its members can be applied to cotton and other cellulosic fibers without the need for mordants [2, 5, 7]. The crucial molecular features of direct dyes are (a) long, linear planar geometries and (b) multiple substitution with negatively-charged sulfonic acid groups as depicted in Fig. 6. Sodium chloride or sulfate is added to the dye bath to enhance dye adsorption. Dye geometry enables close approach to the polymer chains of the substrate. Intermolecular forces that operate at short distances can therefore become significant, aided by the large surface area of the molecule. While diffusion rates of dye into fiber tend to be low because of their large molecular size and propensity to aggregate, diffusion rates out of

Colorant, Textile, Fig. 6 Structural features of CI Direct Red 81

the dyed cellulose during washing are also small so that wash fastness is moderate. The class is dominated by azo derivatives: disazo dyes for yellows to blues and polyazo colorants for blue, green and neutral shades. Direct dyes are used for their economy where wash fastness is not critical [8, 10].

Disperse Dyes

These non-ionic colorants are hydrophobic like the synthetic textile substrates to which they are applied [9, 10]. Originally developed for cellulose acetate fibers, their principal use is the coloration of polyester: the importance of this textile material means that disperse dyes have become one of the two most important types of textile colorant [5, 8]. They have only sparing water solubility and so are applied as fine dispersions in water (apart from when they are used in transfer-printing ink films). Dye particle sizes are typically distributed in the range of around 0.1–1 μm diameter for supply either in solid or liquid dispersion form. These forms are prepared by milling dyes as a suspension in an aqueous solution of dispersing agent. The latter is usually an anionic polymeric material, such as a lignosulfonate or an arylsulfonic acid condensate, that inhibits re-aggregation and maintains dispersion stability. To obtain the micronized dye in solid form, the aqueous dispersion is spray-dried after milling in order to remove the water. During exhaustion dyeing, a small proportion of colorant is in aqueous solution: it is from this phase that dye is adsorbed onto the textile and diffuses within it. Colorant lost from the aqueous phase is replenished by dissolution of dye remaining in suspension. The micron sizing of dye particles is essential in ensuring that

colorant dissolves at a fast-enough rate and to a sufficient degree. Disperse dyes must have relatively compact structures to enable them to diffuse satisfactorily within hydrophobic textiles, so commercial ranges consist mainly of monoazo and anthraquinone derivatives: the latter are important in the bright red and blue sectors, but the former dominate the rest of the gamut. Several other chemical dye classes are employed but these tend to occupy niches, such as yellow nitrodiphenylamines. Brown and black disperse dyes are usually formulated using mixtures of azo dyes because of the technical and economic difficulties in creating single component colorants of appropriately small molecular size with the desired hue.

Pigments

While used primarily for the coloration of media other than textiles, pigments can be printed onto fabrics. Examples of organic pigments used as textile colorants in this way include yellow acetanilide and red naphthol monoazo derivatives as well as blue copper phthalocyanines [6]. The insoluble colorant is incorporated into a paste, which is applied to the textile fabric by a printing process (e.g. screen, roller, etc.). After curing of the paste, normally achieved by drying, the pigment is physically bound to the fabric. Pigments are also employed in the mass coloration of many types of textile fibers in which the colorant is dispersed in a solution or melt of the polymer prior to fiber formation so that the pigment particles become trapped within the fibers as they are produced. The pigment types mentioned above as well as numerous other chemical classes are employed in this capacity.

Reactive Dyes

These colorants are the only ones that form covalent bonds with the textile to which they are applied [2, 5, 7–10]. While they can be applied to wool, nylon, and silk, reactive dyes for cotton have achieved the greatest commercial success, becoming one of the two most important application classes. After exhaustion or printing onto the cellulosic substrate, the dye reacts with ionized hydroxy groups, furnishing excellent wash fastness. Reactive colorants resemble direct dyes with one or more attached fiber-reactive groups. This geometry favors adsorption and reaction with cellulose, although the reliance on covalent bonding allows greater flexibility in choice of chromogen. The vast majority of reactive dyes are azo derivatives apart from in the bright blue and green shade areas where anthraquinone-, phthalocyanine-, and triphendioxazine-based colorants among others are important [5, 7]. Commercially important reactive groups bond to the substrate either by addition, e.g., vinylsulfone anchors, or by substitution, such as through halogenotriazine functions like that illustrated in Fig. 7.

Sulfur Dyes

These colorants are prepared by heating aromatic compounds with sulfur or a sulfur compound to

produce compounds of large molecular size that contain disulfide ($-S-S-$) linkages between the aromatic components [1, 5, 7]. Dyes of this kind are chemically complex and, in the majority of cases, their structure is unknown. Their application resembles that of vat dyes (see below) [2, 8]. The initially water-insoluble dyes are reduced in the presence of alkali to a water-soluble “leuco” form containing water-solubilizing thiolate ($-S^-$) groups which diffuse into the fiber in the presence of electrolyte. At the end of dyeing, these groups are then oxidized in situ to create a new set of disulfide linkages, producing insoluble colorant which remains trapped in the fiber. Sulfur dyes are widely used for the production of dull deep shades of reasonable wet fastness because of their low cost [10].

Vat Dyes

Members of this class, which are applied mainly to cotton and other cellulosic fibers, generally provide the highest all-round fastness but are expensive, so they tend to be the class of choice when durability is a priority, e.g. production of upholstery [5, 8, 10]. Key aspects of vat dyes are water insolubility and the presence of one or more pairs of carbonyl groups. The class derives its name from the crucial operation during dyeing

Colorant, Textile, Fig. 7 Key features of CI Reactive Blue 15

Colorant, Textile, Fig. 8 Key features of CI Vat Blue 1 (Indigo)

and printing called “vatting” which involves reducing the carbonyl functions of the finely dispersed colorant to produce a water-soluble “leuco” form (see Fig. 8). Once the leuco form of the dye has been applied to the textile, oxidation is then undertaken to regenerate the colored water-insoluble form of the dye within the substrate where it becomes physically trapped. Fastness to washing and light are therefore excellent once loose colorant has been removed by a soaping step. The class is dominated by anthraquinonoid and more complex polycyclic derivatives although indigoid colorants are also important, especially the parent compound Indigo which is the highest volume vat dye (see Fig. 8) [5, 7].

Future Prospects

The enormous variation in both the chemical and physical characteristics of textiles has forced the emergence of a diverse array of coloration technologies. As a consequence, many different types of colorant have been commercialized for application to textiles. Pigments are used in the printing of textiles or in the mass coloration of polymer intended for fiber manufacture, while dyes are applied industrially in different ways ranging from exhaustion dyeing to transfer printing. The wide spectrum of techniques available to a dyer or a printer has only been made possible through the development of colorants that possess chemistries and physical properties tailored for application to specific types of textiles. There is no such thing as

a ‘universal’ colorant that can be applied satisfactorily to all textiles for all intended outlets, nor is one likely to materialize in the near future. It is widely accepted that the chances of new application classes or structural types being introduced are remote. The rise in regulatory costs associated with bringing novel chemical entities to market over the past couple of decades has acted as a brake on the commercialization of new textile colorants. Nevertheless, research along these lines continues alongside incremental work to improve on the technical properties, economy, and environmental impact of existing textile colorants. Despite claims of a renaissance in natural dye usage in textile coloration that continue to appear in the academic literature, such colorants are not a panacea for the disadvantages of synthetic materials owing to unresolved shortcomings associated with manufacture, application, and performance. The fruits of research into structural color, e.g. the design of materials such as cellulosic fibers whose surface structure itself generates color without recourse to use of dyes or pigments, presents a potential existential threat to textile colorants [11]. However, industry will continue to produce and apply synthetic dyes and pigments in the textile coloration sector for many years to come.

Definition

Thermochromism is the property of temperature dependence of the electronic absorption spectrum of a material, resulting in a color that depends on temperature. At one time, the term thermochromism, also known as thermochromatism, was reserved for isolated compounds and their solutions. However, the advancement of the field has led to a broadening of this definition; the term thermochromism now also describes multicomponent mixtures that are able to change color in response to changes in temperature. For both isolated compounds and mixtures, reversibility of the color change generally is regarded as a necessary condition for thermochromic behavior.

Interestingly, thermal copy and receipt paper, which have been the most commercially important thermally responsive color-changing products for the past several decades, undergo an irreversible coloring reaction and therefore do not fall under this narrow technical definition of thermochromism. High technology products such as thermal copy paper and erasable inks, which make use of multicomponent thermochromic *mixtures*, become thermochromic due to the thermal initiation of a secondary color-changing reaction. *Halochromism*, the color change of a compound in response to changing pH, is the temperature dependent auxiliary process occurring in thermal copy paper which causes the color change.

Introduction

Thermochromic compounds change color reversibly in response to temperature changes [1, 2]. Many thermochromic compounds are organic in nature and undergo thermally activated chemical modifications which give rise to the color change. In many cases, the chemical modification is a result of *tautomerism*. Tautomerism refers to reversible structural isomerism that consists of multiple steps usually involving bond cleavage, molecular reconfiguration, and subsequent bond reformation [3]. Thermochromic behavior can be observed in a wide variety of isolated compounds. Common organic thermochromic compounds include crowded ethenes, Schiff bases, spiro-

heterocycles (e.g., spiropyrans, spironaphthalenes, etc.), and macromolecular systems including liquid crystals and π -conjugated polymeric materials [4]. There are comparatively fewer examples of inorganic thermochromism. However, vanadium (IV) oxide (VO_2) has recently garnered much attention from researchers as a potential smart coating material due to its thermally tunable infrared and near-infrared absorption spectrum [5].

Today, significant research efforts in academia and industry focus on the development of new technologies and devices based on multi-component thermochromic mixtures including smart coatings, erasable printing media, and temperature sensors. This article provides a brief review of important examples of thermochromic compounds, followed by a description of the most recent advancements in the field with an emphasis on applications for new high-technology materials. Advanced *thermochromic materials* take advantage of the growing field of *functional dye chemistry*, and a few examples are presented.

Organic Thermochromism

Thermochromic behavior in organic compounds is often caused by thermally activated chemical rearrangements, i.e., *thermal tautomerism*. Some

of the more common examples of tautomerism include acid-base reactions, keto-enol rearrangement, and lactim-lactam equilibria. Tautomerism is usually influenced by changes in temperature and solvent properties such as composition, polarity, and pH, and thermally activated tautomerism can lead to thermochromism.

Bianthrone and Crowded Ethenes

One of the first examples of reversible thermochromism observed in organic compounds was that of bianthrone [2]. The structures of bianthrone and some of its analogues are shown in Fig. 1. Bianthrone's structure can be considered in terms of the planarity of each anthrone moiety (i.e., the upper and lower half of the molecule, as shown in Fig. 1). At room temperature, the anthrone moieties are curved such that the aromatic rings within each anthrone moiety are not coplanar. When the temperature is increased, the central carbon-carbon double bond expands. This slight bond expansion allows the two anthrone moieties to rotate with respect to one another such that the dihedral angle across the double bond approaches 90° . When this occurs, the previously bent anthrone moieties each take a more planar structure as the steric repulsion created by the proximity of the other anthrone moiety is reduced by rotation about the central bond [6].

Colorant, Thermochromic, Fig. 1 (a) The structure of bianthrone and (b) related compound dixanthylene. (c) Bulky groups at the 1, 1', 8, and/or 8' positions would result in nonthermochromic compounds

The increased planarity at higher temperature permits π -conjugation to extend more effectively across each anthrone moiety, decreasing the HOMO-LUMO gap and concomitant electronic absorption energy, and thereby giving rise to a change in color of the compound with a change in temperature. Bianthrone is yellow in the solid (absorbing violet light at low temperature), and green (absorbing red light) in the melt. Substituents play a strong role in determining if these crowded ethenes will be thermochromic. Dixanthylene is colorless in the solid, and green in the melt. Bulky groups at the 1' and 8' positions would cause excessive steric repulsions and prevent the formation of the bent anthrone state, which is required for the color-changing process [4].

Schiff Bases, Also Known as Salicylidene-Anilines

Thermochromic Schiff bases, also known as imines or azomethines, are formed by the condensation of an aromatic amine with either an aldehyde or ketone. The simplest compound in this class, salicylidene-aniline, is generated by the reaction of salicylaldehyde with aniline. The thermochromic Schiff bases exist in a state of equilibrium between two forms, the *enol-imine* and *keto-enamine* forms. For salicylidene-aniline, the enol-imine form is more stable at room temperature (Fig. 2). Increased temperature allows an intramolecular tautomerization to occur: The proton from the hydroxyl oxygen migrates to the imine nitrogen. Due to the rearrangement of the π -electrons, the keto-enamine form has more extended π -bonding than the parent enol-imine, which gives rise to a change in color [7].

Substituent effects play a very important role in this system and define which tautomeric form of the enol-imine—keto-enamine equilibrium dominates. To switch between forms, thermal energy sufficient to exceed the activation energy of the tautomeric reaction must be added to the system. A review of the Schiff bases by Minkin et al. demonstrates the vast variability in this family of compounds, where simple modifications and ring substitutions can push the enol-imine-keto-enamine equilibrium in either direction [8].

Note that photons (light) also can be used to provide sufficient energy to initiate tautomerism. In that case, the process is considered to be *photochromic*. Thermochromic and photochromic properties in this class of compounds were long thought to be mutually exclusive. However, more recent studies have indicated that salicylideneanilines are almost always thermochromic in the solid state and are occasionally also photochromic [9].

Spiro Compounds, Including Spiropyrans

Spiro compounds are arguably the most important class of compounds used in thermochromic applications; halochromic triarylmethane and fluoran dyes are widely used as colorants in multi-component thermochromic mixtures (for example, in thermal receipt paper and erasable printing media) [10, 11]. This class includes spiropyrans, spironaphthalenes, spiropyrans, and fluoran and triarylmethane dyes. Spiro compounds, so named for the “spiro” central sp^3 tetrahedral carbon center that all members share, are subject to numerous tautomeric equilibria including lactim-lactam, acid-base, and the aforementioned enol-keto equilibria. These equilibria result

Colorant, Thermochromic, Fig. 2 Tautomeric equilibrium between enol-imine and keto-enamine forms observed for thermochromic Schiff bases [8]

Colorant, Thermochromic, Fig. 3 Schematic view of the tautomeric equilibrium between a ring-closed spiropyran (SP) and a ring-opened merocyanine (MC) form as observed for spiro compounds [4]

in chemical modifications that have significant impact on the electronic structure, and subsequently, on the color of these compounds [12]. Many *functional dyes* belong to this category of compounds: Some of the more important examples are the triarylmethane dyes (e.g., crystal violet lactone, CVL) and the fluoran dyes [13].

The spiropyrans form one of the longest-known and best characterized classes in this group. Figure 3 shows an equilibrium that is observed commonly in this class of compounds [4]. The spiro center is located within the pyran ring which, upon excitation with thermal energy, can undergo a ring-opening reaction that alters the electronic structure. As a result of the disruption of the spiropyran (SP) form, the molecule undergoes electronic rearrangement giving the merocyanine (MC) form, which is deeply colored (e.g., violet, red, and blue) for nearly all members of this family [2].

An important structural aspect of this class of compounds is that in the uncolored spiropyran form, two or more aromatic moieties are segregated from each other by the central spiro carbon atom. After the tautomeric rearrangement to the more planar merocyanine form, the formerly segregated π -electronic domains are able to form resonance structures which extend across the entire molecule. This delocalization of the π -electronic structure lowers the HOMO-LUMO gap (which would be in the UV typically for the ring-closed structure) and gives rise to the formation of intense color in these compounds. The mechanism for this process is shown in Fig. 4 for di- β -naphthopyran, which was first studied by Dickinson and Heibron [14]. An important observation is that ring-opening leads to a

zwitterion, which has significant implications concerning the solubility of the ring-opened merocyanine form.

Ring-opened spiropyrans usually adopt the quinoid structure as shown in the bottom right of Fig. 4. However, if the R-group on the pyran moiety (see Fig. 3) is a strong electron-withdrawing group, the negative charge on the oxygen in the zwitterionic form will be stabilized allowing the molecule to have zwitterionic character. Substitutive modifications to either of the aromatic functionalities in spiropyrans can significantly modify the thermochromic properties by stabilizing the charges formed in the ring-opened configuration.

Liquid Crystals

A well-known example of thermochromic behavior which results from macromolecular interactions is the thermochromic liquid crystals. Thermochromic liquid crystals can be found in products as diverse as mood rings, “stress testers,” warning indicators, and thermometers [15]. Thermochromic effects have been exploited in many different types of liquid crystals, but only two basic series of liquid crystals have found widespread use in thermochromic applications. The esters of cholesterol (Table 1) were first studied by Reinitzer and led to the identification of the liquid crystalline phase [16]. The ester derivatives of (S)-4-(2-methylbutyl) phenol (Table 2) form the basis of the majority of today’s thermochromic liquid crystal devices.

Thermochromic liquid crystals take advantage of the special optical properties of the chiral nematic phase (abbreviated Ch and/or N*). The nematic phase is formed by calamitic (“rod-

Colorant, Thermochromic, Fig. 4 Mechanism of the ring-opening reaction in the spiropyran di- β -naphthopyran. Cleavage of the spiro carbon-oxygen

bond yields a structure with greater planarity and extended π -conjugation. The compound becomes colored due to this extended conjugation [4]

Colorant, Thermochromic, Table 1 Structure and thermochromic temperature ranges of some cholesterol esters [17]

R	Temperature range of color change
CH ₃ CO ₂ to C ₈ H ₁₃ CO ₂	94–113 °C
CH ₃ OCO ₂ to C ₆ H ₁₃ OCO ₂	94–108 °C
C ₇ H ₁₅ OCO ₂ to C ₉ H ₁₉ OCO ₂	77–81 °C

Colorant, Thermochromic, Table 2 Structure and thermochromic temperature ranges of some 2- and 3-ring 2-methylbutyl phenol esters [17]

R	Temperature range of color change
C ₅ H ₁₁ & C ₈ H ₁₇	–5–0 °C
C ₆ H ₁₃ O to C ₁₀ H ₂₁ O	35–50 °C
C ₅ H ₁₁ -Ph to C ₇ H ₁₅ -Ph	130–140 °C

shaped”) liquid crystals and demonstrates only orientational order; this phase lacks long-range positional order [1]. The angular distribution of the long molecular axes of the calamitic molecules is central to the special optical properties of chiral nematic phase liquid crystals. The most probable direction of the long molecular axes defines the *director* which coincides with the principal optical axis of the uniaxial phase. In the chiral nematic phase, the director spirals about a helical axis. The pitch length, p , corresponds to the distance along the helical axis required for the director to make a full rotation about the helical axis. The pitch length can be on the order of a few hundred nanometers, i.e., the wavelength of visible light [1]. This effect is shown schematically in Fig. 5 [18].

Light reflected by the layer in the chiral nematic phase at location A (see Fig. 5) can constructively interfere with light reflected from the layer at position B (see Fig. 5) if the extra distance travelled (layer A compared with layer B) is an integer number of wavelengths of light. This phenomenon is analogous to Bragg reflection in layered crystalline solids. In such a way, chiral nematic phase liquid crystals act as a diffraction grating, or more precisely, a monochromator. Temperature variations in the sample can cause the pitch length to change via thermal expansion, giving rise to variations in the wavelength of light that is constructively reflected (aka selective reflection). An important practical consideration arises from this selective reflection; light that is not reflected by the liquid crystal must be transmitted or absorbed. If the backing material is lightly colored, any transmitted light can be reflected back through the liquid crystal, interfering with the single selected wavelength of reflected light, changing the color. Therefore, thermochromic liquid crystal devices are almost always printed on black backings to absorb light of wavelengths other than the one selected for reflection [17].

To obtain thermochromic behavior in chiral nematic liquid crystals, the pitch must vary rapidly with temperature. Phase transitions are usually exploited to control variation in pitch. The most common transition exploited is the S-N*

Colorant, Thermochromic, Fig. 5 Pitch length corresponds to the distance required for the director to make a complete rotation about the central helical axis, from layer A to layer B. (Reproduced with permission from *Journal of Chemical Education*, 1999, 76(9), 1201–120. Copyright (1999) American Chemical Society)

(smectic to chiral nematic) phase transition. As the material cools within the N* phase, the pitch elongates (i.e., the liquid crystal becomes more locally structured) and the reflected color changes from blue (at higher temperatures) to red (nearer to the transition temperature). This effect is shown graphically in Fig. 6. Note that further heating of the liquid crystal brings about a transition to the isotropic liquid phase concomitant with a loss of selective reflection and color.

In general, the two important categories of thermochromic liquid crystals behave in much the same way. The major difference can be found in the applicable temperature range for each of the materials. Cholesteric liquid crystals generally have much higher transition temperatures and tend to find applications in

Colorant, Thermochromic, Fig. 6 An illustrative representation of the change in pitch length and corresponding color of a chiral nematic phase liquid crystal above the S-N* transition [17]

Colorant, Thermochromic, Fig. 7 (a) The polymer 3-hexyl polythiophene, an important material for organic electronics, has coplanar thiophene rings at low

temperature. (b) Polydiacetylenes also can display thermochromic behavior depending on the choice of side-chain groups

thermometers on pasteurization equipment, ovens, and warning indicators on hot surfaces. The (S)-4-(2-methylbutyl) phenol derivatives have transitions at much lower temperatures, including physiological temperatures, and find use in thermometers, mood rings, and in refrigerator and food spoilage warning labels. Thermochromic liquid crystal devices can be engineered to behave in both reversible and irreversible manners, with the latter being particularly important if the thermal history of a product (e.g., perishable food products) is of particular importance [15, 19].

Polymers

Highly π -conjugated organic polymers can demonstrate interesting electrical properties resulting from very long conjugation lengths and a high

degree of delocalized electron density. As with conjugated small molecules, conjugated oligomers and polymers are susceptible to thermally induced structural modifications and can exhibit thermochromism. Some common thermochromic polymers include polythiophenes (Fig. 7a), polydiacetylenes (Fig. 7b), and α -conjugated polysilanes [20, 21].

Thermochromism in conjugated polymers arises when sufficient thermal energy causes an order-disorder transition involving the bulky side chains of the polymer. The side-chains in polymers generally keep the polymer backbone organized in some fashion; the backbone bonds tend to be in either all-*trans* or helical conformations. Above a certain temperature, the side chain groups become dynamically disordered and can

no longer keep the backbone chain in its original conformation. The most common transformation is from all-*trans* to *gauche* conformation. Thermochromism results from the change in the HOMO-LUMO gap.

Polythiophenes are widely employed in organic electronics as a conducting layer. They are highly conjugated when the thiophene rings are in a *trans*-planar configuration. Regioregular poly-3-alkylthiophenes (Fig. 7) undergo a reversible color change from red-violet to yellow when heated under vacuum. This change arises from weakening side-chain interactions that are no longer able to maintain the coplanarity of the thiophene rings, resulting in twisting along the chain, a decrease in conjugation, and a change in wavelength of light absorbed [22].

Inorganic Thermochromism

Thermochromism in inorganic materials can have many different origins: changes in ligand geometry, changes in metal coordination, changes in solvation, changes in band-gap energy, changes in reflectance properties, changes in distribution of defects in the material, and phase transitions [23].

An example of thermochromism arising from a phase transition is the compound Ag_2HgI_4 . At room temperature, the compound adopts a tetragonal crystal structure and is yellow. Upon heating to 50 °C, Ag_2HgI_4 undergoes a first-order phase transition from tetragonal to a cubic phase concomitant with a color change to orange. Upon further heating, it undergoes a gradual (second-order) order-disorder transition to a phase in which the silver ions become mobile in the lattice and the color of the compound changes to black. Therefore, across a temperature range from 25 °C to 75 °C the material changes from yellow to orange to black [24].

Reversible thermochromism also can be observed for inorganic compounds in solution. In solution, the color changes are often associated with modification of the solvation sphere, changes in coordination number, or ligand exchange with the solvent. A commonly cited example is CoCl_2 in water which is blue at room temperature and green at 0 °C, as shown in Fig. 8 [25]. As the system is heated, the Co(II) coordination changes from octahedral to tetrahedral and is coupled with ligand exchange. This structural change alters the electronic field experienced by the central Co^{2+} as a function of temperature, changing the wavelength of light absorbed, and giving rise to thermochromism.

Perhaps the most interesting inorganic thermochromic compound is vanadium (IV) dioxide, VO_2 , which undergoes a semiconductor to metal transition at 68 °C. The transition modifies the absorption spectrum in the infrared and near-infrared regions. Vanadium dioxide is infrared transmissive below ~68 °C and infrared reflecting at higher temperatures [5]. Vanadium dioxide is being considered for use in smart coatings which would allow visible sunlight to pass through a thin film coating but block infrared radiation, thus reducing building cooling requirements [26]. Inorganic thermochromic compounds are of great interest for building coatings owing to their stability to light, which is substantially better than organic thermochromic compounds which are notoriously susceptible to decomposition under extended light exposure [27].

Thermochromic Materials

The term *thermochromic materials* refers to multicomponent mixtures of chemicals which, although not necessarily thermochromic

Colorant, Thermochromic, Fig. 8 The equilibrium form for Co^{2+} in aqueous solution and in the presence of Cl^- changes from green to blue upon heating from 0 °C to room temperature, resulting in thermochromism

individually, create a thermochromic system when mixed in the appropriate proportions. Some popular examples of commercial products incorporating this type of thermochromic material are the Pilot Frixion erasable pen, the Coors Light beer bottle label, and the NHL hockey puck [28, 29]. The color of ink from the Frixion pen can be erased thermally by the friction created by rubbing the eraser head on the page [follow this link for a video <https://youtu.be/NbtcVg0m5Q8>] [28]. Similarly, the label on the Coors Light beer bottle contains a color-changing dye system that reversibly changes from colorless to blue upon cooling the container to below $\sim 6^{\circ}\text{C}$, and the NHL hockey puck label changes from violet to colorless to indicate that a puck has warmed and requires replacement [29].

In such mixtures, a color-forming agent, the *chromophore*, also known as *leuco-dye*, reacts with a color-developing agent, the *developer*, to initiate the color-changing reaction. The color-

changing reaction also is controlled by another component of the mixture, usually referred to as the *cosolvent*, which forms the bulk of the mixture. The cosolvent melts, and its melting point determines the color-change temperature. The cosolvent's interactions with the other components also determine if the colored form of the mixture occurs at high or low temperature [30].

Significant effort within industry has been aimed toward development of thermally erasable printing inks and toners for large-scale printing in an office setting [31]. National Cash Register Co. developed an irreversible "thermochromic" receipt paper in the 1950s using the spiroactone dye crystal violet lactone (CVL) as the chromophore [18]. The closed ring SP form of CVL is colorless; upon interaction with an acidic compound (or an electron acceptor), the lactone ring opens forming the intensely blue, ring-opened MC form (Fig. 9). Attaplagus clay and phenolic

Colorant, Thermochromic, Fig. 9 Ring-opening reaction of crystal violet lactone (CVL) in the presence of an acidic developer. The ring-opened charged form has multiple resonance forms, only two of which are shown here

resins were originally used to develop the color, although more recently, phenolic compounds such as bisphenol A (BPA) have been the developers of choice in the United States.

Most of the receipt paper used today in commercial enterprises employs this type of technology, although the chemicals employed are changing. Fluoran dyes are generally used to produce the black color of modern receipt paper and bisphenol A is being replaced by other, less harmful, and phenolic compounds. These compounds include Wincon D8, BASF Pergafast PF201, and to a lesser extent other bisphenols including bisphenol S and bisphenol AF [32].

Today, the color-forming components are printed onto the receipt paper in two layers, one containing the chromophore and the other containing the developer. Both layers are mainly composed of a heat-fusible material called a *sensitizer*. Heating the receipt paper causes the sensitizer to melt, placing the chromophore and developer into intimate contact and thereby initiating the coloring reaction. Although this process is technically not thermochromic due to the lack of reversibility, the widespread use of thermal receipt paper warrants its inclusion in this section [33].

An interesting commercial development from Japan is Toshiba's e-Blue erasable laser jet toner. The toner is composed of a blue colored spirolactone dye and phenolic developer embedded in a polymer matrix. When printed, the toner is blue. Heating a printed page will cause a decolorization reaction in which the developer is segregated from the dye, returning the initial uncolored state of the dye and erasing the printed image [34]. The potential benefits of reducing the amount of paper that enters the recycling waste stream are substantial, although poor resistance to color fade and low image quality thus far have precluded wide usage of such rewritable printing media. These examples of thermochromic materials also fall under the umbrella of the broad *functional dye* field and are discussed further in another chapter in this text.

The previously mentioned Pilot frixion erasable pen ink represents a special case of reversibly thermochromic materials. The cosolvent component of the Pilot Frixion erasable pen demonstrates a large hysteresis between its melting and crystallization temperatures [28]. To maintain the hysteresis effect, the thermochromic material is microencapsulated in a rigid polymeric shell (making a "thermochromic pigment"). The colored form of the thermochromic material occurs when the cosolvent is solid, and the colorless form occurs when the cosolvent is liquid. The large hysteresis of the melting/crystallization temperature of the cosolvent permits both the colored and colorless/erased states to exist at room temperature (the erased state is metastable), allowing for an erasable ink. Extensive research activity in the writing instrument industry is aimed at developing new cosolvent components with large hysteresis. Companies including BIC (Gelocytion Illusion) and Uniball (Fanthom) have also recently developed erasable inks [35, 36].

Thermochromic Colorants

Thermochromic leuco dyes and liquid crystal systems are used in the textile industry for both functional and artistic purposes. The breadth of variation in leuco dye structure permits the formulation of thermochromic products demonstrating an amazing array of colors. The choice of cosolvent allows for precise control of activation temperatures (i.e., the color-changing temperature). Companies supplying thermochromic products can design products to suit the needs of the textile manufacturer. Virtually, any color imaginable can be produced by precise mixing of primary colors (e.g., red, green, blue, etc.), while clever selection of activation temperatures can result in interesting and esthetically pleasing color-play effects [37].

Thermochromic colorants need to be isolated from their surroundings prior to use in textile applications in order to preserve the intended coloring behavior of the colorant system. To this end, microencapsulation is used to isolate the thermochromic system, with the *in situ and interfacial*

polymerization methods being the most common. The microcapsules are dried to form a powder, after which they are usually referred to as *thermochromic pigments*. The pigments can then be made into slurries, emulsions, or pellets, or dispersed into inks and paints, or applied directly to a fabric.

One of the major problems concerning the use of thermochromic pigments is dilution of the dye throughout the processing steps; final dye concentrations can range from 3–5% for pellets to 15–30% for inks and paints [37]. Other problems include poor stability against UV radiation (e.g., photo-bleaching), poor resistance to the effects of water and detergents, the cost of the thermochromic material, and for some, toxicity of the components [27, 32]. In the case of liquid crystals, the fiber onto which the thermochromic pigment is printed must be black to prevent unwanted reflection effects [38]. Additionally, the microencapsulation process can disrupt carefully engineered interactions in multicomponent thermochromic mixtures (i.e., dye, developer, and cosolvent mixtures) such that the final microencapsulated product does not behave in the same way as the isolated system.

The use of thermochromic colorants in the textile industry has been mainly limited to novelty applications (e.g., Hypercolor T-shirts). More recent textile applications have been focused on using the thermochromic effect for artistic purposes [38]. Many of the thermochromic artistic works reviewed by Christie et al. [38] employed fabric-bound, microencapsulated thermochromic dyes coupled with heat-producing microelectronic devices to initiate the color-changing behavior. Smart materials including electronics-coupled textiles [39], multisensory interactive wallpapers [40], surface coatings containing heat-storing *phase change materials* (PCMs), and soft-woven thermochromic fabrics [41] have been reported. These artistic applications of thermochromic colorants demonstrate the important link between scientific and technological development and the creativity of the artistic world.

Coloration, Fastness

Martin Bide

Department of Textiles, University of Rhode Island, Fashion Merchandising and Design, Kingston, RI, USA

Definition

Humans use a range of technologies to produce color: solid surfaces are painted, paper and packaging is printed, color images are viewed on screens, and they color the textiles and leather used in their clothing and around homes. Screen color is transient, and few paper products are expected to last long. More durable color is found on painted surfaces and textiles, and the color is provided to them by colorants. That durability is expressed as “fastness.”

Colorants, with the minor exception of interference pigments, have chemical structures that efficiently absorb light and are thus strongly colored. Present in small amounts, they provide their color to an item. That color may change for a number of reasons. Some transient changes can occur, such as when an item becomes wet, or if the colorant undergoes reversible structural changes under the influence of heat (thermochromism) or light (photochromism). Beyond that, if a colored item maintains its color, it is said to possess fastness. Otherwise, the color of the item may change when either:

- The colorant remains in place but is permanently changed or destroyed.
- The colorant is unaltered, and maintains its color, but is removed, for example, by washing.

Such a change or loss of color is described as a *lack* of fastness. If the colorant is removed, for example, during laundering, it can stain other items with which it comes into contact. Even when the color of the original item is not appreciably altered, this is also considered a lack of fastness.

Color Fastness May Thus Be Defined as the Resistance to Change or Removal of the Color of an Item Under End-Use Conditions

Colorants are divided into dyes and pigments. The difference between them affects both their application and the likelihood of their permanence (Colorant, Classification).

A pigment consists of molecular aggregates, usually in the micron range, with minimal solubility in any solvent with which it is likely to come into contact with (► [Pigment \(Organic and Inorganic\)](#)). Its removal by dissolution is therefore unlikely. If a few of the pigment atoms or molecules on the surface of an aggregate particle are removed or changed, the overall color of the particle (and hence of the substrate it is coloring) is little affected. Low solubility and particulate nature thus mean that fastness in coloration by pigments is readily achieved.

In contrast, a dye is characterized by its solubility, most often in water, in its application (► [Dye](#)). In many cases its resistance to removal derives from the forces that drive its absorption by a substrate, and it remains soluble when the colored item is in use. The details are discussed in greater depth below, but the solubility may limit the resistance of the colorant to removal, and the monomolecular dispersion makes the effect of any removal or destruction more apparent.

Dyes are little used for non-textile items. Pigments have some use on textiles, but dyes and textiles are largely mutually inclusive. Solid surfaces typically do little flexing or moving, whereas textiles face a greater range of challenges than most other colored objects: as clothing they must have sufficient flexibility to move with the wearer and be soft enough not to irritate. They rub against each other. Curtains hang in sunny windows. Textiles are regularly cleaned and often must withstand hot water and detergent or the solvents used in dry-cleaning. For these reasons, the subject of color fastness is most widely studied for textiles. As discussed below, truly permanent color is an unrealistic expectation, and the extent to which color change is acceptable varies widely and is influenced by the cost of the item, the cost of replacing it (or its color), and the possible effect of the color loss on other items. Problems of

fastness are therefore strongly associated with dyed textiles, and fastness in other colored materials is often tested using methods and principles drawn from textile tests.

Overview

As outlined in the definition, the color of an item may change when either the colorant remains in place but is permanently changed or destroyed, or when the colorant is unaltered and maintains its color, but is removed. These two cases are considered below.

Color Change: Colorant Destruction

The colorant on an item may undergo a chemical reaction that changes or destroys its color. Such a change is perceived as a lack of fastness. The reaction may take place slowly and only become apparent after a long period of time or may be quite rapid.

The former relates most often to the chemical reactions that occur as a result of exposure to light. Absorption of light raises a colorant molecule to an excited state in which condition it is susceptible to decomposition, or reaction with oxygen, water, or other available reactants. The reactions involved are complex. They have been the subject of extensive study but much remains to be fully understood: the factors that affect the reaction are many and varied (light intensity, spectral power distribution, temperature, humidity, etc.); it is also clear that color change is not simply a property of the chemical identity of the colorant alone, but is affected by colorant-substrate interactions, by colorant aggregation, and (in mixtures) by colorant-colorant interactions [1, 2]. The same dye can have different fastness properties on different fiber types. Pigments are less involved in these external interactions, but their physical form (particle size, crystalline form, etc.) may affect their fastness.

Whether dye or pigment, for a constant exposure, the destruction of colorant occurs at a fairly constant rate. The effect on the color, however, is not constant. A darker color, resulting from a greater amount of colorant, will be affected less

by a given exposure than a light one, where the same amount of colorant destroyed represents a greater proportion of the colorant present. In other words, a pale shade of a given colorant will have lower fastness to colorant destruction. This is in contrast to the lack of fastness represented by staining as a result of colorant removal discussed below.

The more rapid destruction of dye is usually the result of exposure to a chemical agent: most obviously this might be sodium hypochlorite or hydrogen peroxide used as a bleach, but other chemicals such as benzoyl peroxide used in skin medication will effectively decolorize many dyes. Again, pigments are less prone to such reactions, given their particulate nature and insolubility.

Color Change and Staining: Colorant Removal

Color may be removed from an item, particularly a textile, for a number of reasons. Unlike the case of colorant destruction, the color remains, and the removed colorant may color an item with which it comes into contact: such staining is a component of (a lack of) fastness. For reasons that will become clear, once again, this is best examined from the point of view of dyes.

Dyes are applied to textiles in a number of ways: batch dyeing, continuous dyeing, and textile printing (► [Coloration, Textile](#)). The principles of the interaction are common to all, but best illustrated in the case of batch dyeing [3, 4]. In a batch dyeing process, dissolved dye molecules are preferentially sorbed from the external dye solution at the fiber surface and penetrate the interior of the fiber as a result of the intermolecular forces that comprise the “substantivity” of the dye. The relative motion of the dyebath and the substrate replenishes the dye-depleted solution at the fiber surface, and the rate-determining step of the overall process is typically the rate of sorption into the fiber. If dyeing conditions are maintained long enough, an equilibrium is established between dye in fiber and dye in solution, and all fibers are fully and equally penetrated. In practice this situation is rarely achieved, and microscopic observed examination of a dyed textile will reveal fibers and yarns with only partial penetration of dye. Such microscopic unlevelness is tolerable.

An essential requirement of a colored textile is that the color be level at the macroscopic scale. Assuming a clean and absorbent substrate from earlier preparation processes, and homogeneously dyeable fibers, levelness results from a balance of two possible routes. Either the dye is absorbed in a level manner, or an initial unlevel sorption is made level by the migration of dye [5].

The substantivity of the dye is based on the molecular size and shape of the dye and functional groups present. Together, these allow the formation of a range of non-covalent bonding that makes up the attraction of dye for fiber and which enables dyeing to take place [4]. If nothing else happens, these same forces will provide the fastness the dye has in use, in competition with the solubility of the dye in the particular medium (e.g., laundry liquor).

For fastness (as resistance to removal), a high substantivity (strong dye-fiber bonding) is required. But dyes with high substantivity do not migrate readily, and if initial application is unlevel, it is difficult to achieve levelness via migration. To use a high-substantivity dye, the dyer must control the initial uptake (“strike”) of the dye to be as level as possible. For a given system (machine, dye, fiber), dye uptake can be controlled by control of temperature (rate of rise and ultimate temperature), time, and dyebath conditions of ionic strength (salt) pH, and auxiliaries that moderate the dye-fiber interactions (often surfactant based). However, the demands of levelness may require that lower- substantivity (and thus less fast) dyes be used.

As discussed earlier with colorant destruction, the fastness of a particular dyeing will vary with the depth of shade. For the case of colorant removal, a dark shade will exhibit lower fastness than a pale one: the same percentage of colorant removed from a dark shade will have the propensity to stain more heavily than from a pale shade.

For some dye-fiber systems, the substantivity of the dye that drives dyeing is all that provides fastness in later use. Most notably, acid and metal-complex dyes on protein and polyamide fibers (wool, silk, and nylon) direct dyes on cellulosic fibers and disperse dyes on acetate. In essence, a subsequent aqueous challenge represents the

equivalent of a dyebath and the (beginnings of) reestablishment of an equilibrium in which some proportion of the dye is lost from the substrate.

Several dye-fiber systems have fastness attributable to reasons beyond those provided simply by the dye-fiber interactions. Disperse dyes on polyester have fastness greater than the same dyes on acetate. The high glass transition temperature (T_g) of polyester means that practical dyeing takes place only at temperatures considerably higher than that of boiling water: these are found in pressure dyeing machinery. After dyeing (and in use), the fiber is cooled below T_g , and the dye is essentially trapped in the fiber: the inaccessibility of the dye to outside agencies is reflected in the use of “reduction clearing” to remove any surface deposits of the low-solubility dye. Similar arguments apply to the fastness of basic dyes applied to acrylic fibers.

While a dye must be soluble during application, greater fastness can be achieved if the dye is later converted (or reverts) to an insoluble or less soluble form. This form of the dye may also comprise molecular aggregates and/or larger molecules for which physical entrapment may contribute to the fastness. Vat dyes for cellulosic fibers are produced and sold in their insoluble form and must be chemically reduced to a soluble and substantive form for application. Once in the fiber, they are oxidized to their original insoluble form and forms aggregates inside the fiber: essentially they are now pigments. Several dye types are formed inside the fiber as low-solubility moieties as part of their application. Sulfur dyes for cellulosic fibers are supplied in reduced form; and once applied, they undergo a similar oxidation to vat dyes to form a low-solubility dye. Azoic colorants are generated by reaction within the fiber of a soluble coupling component and a soluble diazo component. The resulting azo dye is insoluble and, like a vat dye, aggregates into pigment form. Mordant (“chrome”) dyes on wool rely on a reaction of dye and mordant in situ within the fiber to form a low-solubility complex of good fastness, and its fastness is enhanced by the entrapment of a physically large molecule.

A further reason for additional fastness may arise from the presence in the dye of functional

groups capable of reaction with the substrate to form covalent bonds. So-called reactive dyes achieve their fastness in this way and since their introduction in 1956 have become the dominant dye type for cellulosic fibers, with additional usefulness for wool dyeing where they can replace the mordant dyes and their associated use of heavy metals [6]. It should be noted that the reaction efficiency is not 100%, and at the end of the dyeing process, any unfixed dye that is not removed by washing will be held only by the forces of substantivity and may be readily removed in later use. In such a case the dyeing as a whole will be considered to have poor fastness.

Achieving Fastness

Colorfastness, whether as resistance to destruction or resistance to removal, is largely achieved by choice of colorant. Dye manufacturers will supply customers with “pattern cards” of materials colored with individual dyes, together with the results of key fastness tests (see below) conducted on those materials. Colorists may thus select colorants that are likely to meet fastness requirements, although as mentioned earlier, the depth of shade will affect the fastness achieved. Resistance to removal may additionally depend on the ability of the process to eliminate any dye that is not fixed or that is loosely held on the fiber surface.

Pigments are used for textiles in one of two very different ways. A pigment can be added to the polymer melt or solution used to form manufactured fibers in the same way that a pigment is added to a melt used to mold plastic items. Subsequent solidification traps the pigment within the polymeric matrix. Fibers colored this way are among the most colorfast of all. However, for textiles, the time between fiber manufacture and ultimate sale may be a year or more, and the holding of multiple color stocks of fiber and yarn means that this coloration method is of limited use in this context.

Pigments can also be bound to a textile material by use of a polymeric binder: this is akin to the

application of paint to a surface. The fastness of such colored materials is related to both the colorant and the binder and the strength of the pigment-binder-fiber interactions [7]. Once again, textiles tend to face greater challenges as they flex and move.

Fastness Testing

The permanence of color in an item is desirable, but the challenges it might face in use are many and varied. It is unrealistic and expensive to demand the best fastness in every case, so compromises are inevitably made. The questions then become, what are the likely challenges this item will face? How well *should* it be able to resist them? How well *does* it resist them? The answer to the first derives directly from the intended end use, while the answers to the second and third require some way of presenting the challenge and assessing the resistance. The most realistic way to do this is to conduct a trial with the item in its intended use to see when and how failure occurs. Such real-life trials are occasionally performed, but they are very expensive and take a long time to produce results. Standardized laboratory fastness testing provides an economical and useful alternative. Standard test methods are developed that are designed to approximate to a single real-life challenge and to predict how an item will respond. Such tests typically provide results rapidly, either because the challenge itself is a rapid one (e.g., color being rubbed off) or because the test accelerates the challenge (e.g., using a very intense light instead of real daylight).

A fastness test is developed to provide the challenge and a way of assessing the result. The result is then compared to a requirement that forms part of an overall product specification. The tests may be widely applicable or represent a challenge that is more specific. Tests are developed by standard setting organizations. Much of the original work to develop these tests for textiles was carried out by the Society of Dyers and Colourists (SDC) [8] in the UK and the American Association of Textile Chemists and Colorists

(AATCC) in the USA [9]. With the rise in global trade, fastness tests have become more international, and many countries now rely on tests published under the auspices of the International Organization for Standardization (ISO) [10].

A good test should be valid: the property it measures should have some real-life relevance, and the test should predict in-service suitability. Additionally, a good test should be simple in terms of how it is performed and how easy the instructions are to understand. It should also be reproducible giving the same results from operator to operator and laboratory to laboratory. In some cases, the control of test conditions may be difficult, and standard fabrics of known susceptibility are used as control materials.

Issues of environmental, health, and sustainability have come to the fore in recent years. Several certification schemes are intended to reassure the consumer that an item has been produced in an environmentally friendly manner and that it does not contain (or will release) substances of concern. Colorants are among such substances, and the measure of colorant release is often based on standard color fastness testing. Thus, for example, a range of color fastness tests is included in the OEKO-TEX 100 certification [11] and in the Global Organic Textile Standard [12].

Testing for Fastness: Challenges

As discussed earlier, fastness tests are designed to reproduce the challenges that a colored item would face in real life. Again, the subject tends to emphasize textiles. Some tests relate to challenges faced in the sequence of manufacturing steps that a textile item undergoes before it gets to the consumer. Most relate to the challenges encountered after the item is sold: these can be divided into those met when the item is being used and those involved in its cleaning or refurbishment. Full details of the tests are sold by from the relevant standard setting organizations. The titles and scope are available in texts and on the organizations' web sites [13–15].

Fastness to (Textile) Production Processes

Textiles woven from multicolored yarns may be scoured and may include a white portion that requires bleaching, and thus a test for fastness to bleaching may be needed. Mercerizing can alter color. Dry heat can cause color changes. Wool undergoes a variety of wet treatments: tests determine the color changes caused when wool is carbonized, boiled in water, bleached, set with steam, or milled. The fastness challenges of the last are reflected in the naming of certain acid dyes that will withstand this process as “milling acid dyes.”

After makeup, garments may be pleated or hot-pressed: these can cause thermochromic or sublimation-based color changes. Silk fabrics may be degummed in hot alkaline soap solution, and a fastness test can predict any changes to colored materials that undergo this process.

Fastness in Use

In use, garments may be rubbed, and their color transferred to another item: fastness to rubbing (also known as “crocking”) is one of the most common tests.

Spots of liquid can cause a color change, either by moving dye within the textile or removing the dye and transferring it to an adjacent material. Thus there are tests for spotting by water, dry-cleaning solvent, seawater, perspiration, acids, and alkalis. Swimming pool water with chlorine represents a destructive challenge.

Atmospheric contaminants, notably ozone and oxides of nitrogen (“burnt gas fumes”) derived from combustion and sunlight, can destroy colorants.

Light represents a particular challenge. Real-life exposure is both slow to produce change and is highly variable (but such real-life exposure is included among standard tests). More usually, an accelerated test uses a xenon arc lamp and controls the temperature and humidity of exposure. The test may be extended by the inclusion of water sprays to cover “weathering.”

Fastness to Refurbishment

Textile items get dirty and require periodic cleaning. The processes to be used are given in a care label, and the suggested cleaning method should have been shown by testing to be appropriate to restore the item to an acceptable level while not causing any damage. However, such refurbishment represents another set of challenges to the color.

Laundrying is conducted in aqueous surfactant solutions with agitation. The details can vary considerably: the detergent (type and amount used), the temperature, the amount of water and the extent of agitation (based on the type of machine used), the nature of the materials used to make up the bulk of the load (“ballast”), and the presence or absence of bleach. The tests to assess fastness reflect this variation in practice. Full-scale laundryings, repeated three or five times, may be used, but since each item should be tested individually to avoid possible confusion in results, an accelerated test is used. A small sample, usually with a standard multifiber adjacent fabric, is agitated in standard detergent solution in a small cylinder for 45 min or so. The effect on color will approximate to that obtained in five real cycles of laundrying. Similar considerations apply to dry-cleaning.

Ironing can affect color: tests examine the effects of dry, moist, and wet heat.

Assessing the Results of Fastness Tests

The tests produce color changes and thus assessment of the results is an assessment of color difference [16]. This might be the difference between the original color and the challenged color or the difference between an unstained fabric and one stained by color removed from the test sample. Color difference assessment has been widely studied for judging colors for acceptable closeness to a standard color (“a match”). That use concentrates on small color differences and is as much concerned with the quality of difference as the quantity of difference. However, the assessment of color differences from fastness testing covers a much wider (quantity) range of color differences and is rarely

Coloration, Fastness,

Fig. 1 Coloration fastness:
AATCC gray scale for color
change. (Copyright
AATCC)

concerned with the quality of difference. These two aspects of color difference measurement have thus tended to go their separate ways.

The results from a fastness test can be assessed subjectively, by reference to physical color standards ("gray scales") or objectively, based on spectrophotometric or digital camera measurements. Physical gray scales have been so extensively used that even when an instrument is used, its output is converted to gray scale ratings.

Gray Scales

The use of physical standard color difference pairs has long been standard practice in fastness testing. These physical standards include a range of difference pairs, from small to quite large. There are two gray scales. One is used to assess a change of color,

and the second is used to assess the extent to which a white material is stained. The gray scale for color change (Fig. 1) consists of pairs of neutral gray chips, one of the pair being a constant gray color, with the second ranging from the same to very different arranged in order of increasing difference. The pair with no difference is labeled "5," and the increasingly different pairs are 4.5, 4, 3.5, 3, 2.5, 2, 1.5, and 1.

The gray scale for staining is similar, but the constant color is white, and the increasing difference is provided by successively darker grays (Fig. 2). In addition to the two basic gray scales, for color change and for staining, AATCC has produced a "chromatic transference scale" (Fig. 3). This is used mainly in the assessment of the staining produced in rubbing fastness tests.

The correct use of each of these scales is described in the relevant ISO and AATCC

Coloration, Fastness, Fig. 2 Coloration fastness: AATCC gray scale for staining. (Copyright AATCC)

documents. The angle of viewing, the quality and intensity of the illumination, and the masking of the test specimen/gray scale pair are specified to eliminate variables and increase interlaboratory agreement.

Instrumental Color Measurement of Fastness Test Data

A numerical color difference equation might reproducibly express the color change or staining resulting from a fastness test. The need for this to correspond to human visual data over a wide color range and to make it agree with the results generated visually with gray scales has made this somewhat challenging. Nonetheless, while some deficiencies are recognized, mathematical

formula for gray scale ratings derived from spectrophotometric measurements or digital camera data are published and used. Work to develop better formulae continues.

Conclusions

Color is an important property of many items, and its durability in items that are expected to last over a period of time is a matter of concern. Textile colorants have the greatest potential to produce unwanted changes in the textiles they color and to stain adjacent materials, and textiles are subject to the greatest range of potentially damaging agents. Thus color fastness testing is most widely studied and performed on textiles. The tests reflect real-life challenges encountered in textile processing,

Coloration, Fastness, Fig. 3 Coloration fastness: AATCC chromatic transference scale. (Copyright AATCC)

in use, and in care, and many of them are accelerated. ISO and AATCC are the most active organizations in the development of such tests.

The tests require a measurement of the changes produced by the test challenge and the stains caused by removed color. For many years, measurement has been based on visual comparison with standard gray scales. Compared to other situations involving color assessment, the adoption of instrumental methods to assess fastness results has been slow. Standard methods for such instrumental assessments are in place, if yet to be widely adopted.

Definition

The coloration of hair is a long-standing practice that can be traced back to the Egyptians who used Henna to impart color to their hair [1]. Today, hair dyes are used by billions of individuals dissatisfied with the natural, and in many cases, graying of their hair. Many temporary, semipermanent, and permanent hair dyes – all synthetic in nature – are commercially available, to offer the consumer diversity in color options and performance levels. Permanent hair dyes are the most popular dyes,

because they offer the consumer the best degree of permanence to washing and gray coverage. Permanent hair dyes are formed inside the hair fiber via an oxidation of precursors that results in the formation of oligomeric dyes. These dyes are too large to be desorbed from the hair fiber during the washing process. Over the last few decades, permanent hair dyes, in particular the precursors (e.g., *p*-phenylenediamine or PPD) used to develop them in hair, have been scrutinized for their genotoxic and skin sensitization potential. Thus, efforts to design environmentally friendly precursors and coloration technologies have been investigated in recent years.

Overview of the Dyeing of Human Hair

Despite the thousands of dyes that can display substantivity toward keratin-based fibers, only a few are suitable for the commercial coloration of hair [2]. A key limitation is the temperature of dyeing. Though keratinic fibers such as wool can appreciably swell in water at temperatures exceeding 75 °C, the human scalp cannot withstand such high temperatures [2]. Consequently, dyeing is performed at a maximum temperature of 40 °C [3–6]. Dyeing times vary, but generally do not exceed 40 min [2]. To penetrate the hair, the dyes must be soluble in water, not too large, not strongly aggregated in solution, and contain few anionic groups [2]. Also, the dyes should be stable to air, light, friction, perspiration, chlorine, other cosmetic treatments, and the pH at which dyeing is performed [3, 5]. Perhaps of more importance to the consumer, the dyes must be appealing and removable, if desired [2], and impart minimal damage during application [5]. The dyes should also be toxicologically safe [2–5], not only for the consumer but also for the hair stylist who applies the dye [5].

Compared to the synthetic hair dye coloration process, coloration using natural hair dyes is often longer and requires more dye to achieve a satisfactory shade depth [7]. Also, the resultant hair color is typically unstable to light and shampoo treatments [8]. Thus, synthetic dyes have dominated the global hair dye market since the

development of the first dye [7, 9]. Synthetic hair dyes can be categorized as temporary, semipermanent, and permanent. As their names imply, these classes are based on the resistance of the dyes to removal during shampooing or their “permanence.” In this regard, temporary dyes last through only one or two shampoos, while semipermanent dyes last up to six shampoos [4, 5, 10, 11]. Permanent dyes essentially last until new hair growth appears, which is every 4–6 weeks for the average consumer [3, 11, 12]. Dyes that are less permanent tend to be larger and adsorb onto the surface of hair [13] or diffuse only into the cuticle, or the outermost region of the hair fiber [11]. The precursors that give rise to permanent hair dyes are capable of diffusing into the cortex (an inner region of the hair fiber), due to their small size, where they react to form oligomers that aggregate and become too large to be desorbed from the hair [2, 4, 5, 12]. In each case, some dye can remain adsorbed onto the surface of hair [11, 13]. Dye adsorbed onto the surface or within the outer layers of hair can more easily be removed upon shampoo treatment [1, 4, 5, 9–11], especially if dye is weakly bound and the cuticle is damaged (more porous).

Synthetic hair dyes can also be classified based on their chemistry as non-oxidative or oxidative, the latter of which describes the permanent hair dye formation process that involves the oxidative coupling of precursors to produce the dyes within hair. Temporary and semipermanent dyes are

designated as non-oxidative dyes, because they do not require an oxidant for color formation [1, 9]. Temporary dyes are ionic in nature, while semipermanent dyes are either ionic or nonionic. Examples of temporary and semipermanent dyes can be found in Hair Dye Substance Database recently developed by Williams and co-workers [14], which is available for download at https://figshare.com/articles/Hair_Dye_Substance_Database_HDSD_/5505856. Each of the dye classes, with respect to their diffusion into hair after dyeing, is schematically represented in Fig. 1.

Hair Dye Diffusion

The principle mechanism of dye diffusion in hair has been a controversial topic [15–19]. Two theories are recognized – intercellular and restricted transcellular (see Fig. 2), and it has been suggested that they coexist [20, 21]. A key difference between the two theories is the location at which the dye first penetrates the fiber. In today’s more accepted theory [19, 20], intercellular diffusion, dye penetrates the fiber initially through the intercellular cement or between cuticular cells parallel to the hair fiber [15, 16, 22–24]. Dye diffuses into the regions low in sulfur content and then into the regions high in sulfur content [15, 16, 22–24]. The intermacrofibrillar cement in cortical cells can also provide a diffusion path

Coloration, Hair, Fig. 1 Schematic representation of dye diffusion into hair fiber cross-sections based on dye type

Coloration, Hair,

Fig. 2 Schematic representation of the intercellular and restricted transcellular hair dye diffusion mechanisms. (Note: the endocuticle spans the length of the cuticular cell; large, hydrophobic dye molecules are shown in red “squares”, and small, hydrophilic dye molecules are shown in blue “circles”)

[24]. Contrarily, restricted transcellular diffusion occurs via the penetration of dye normal to the hair fiber through the cuticular cell edge, namely, through the endocuticle and cell membrane complex (CMC) [19]. The preferred mechanism for large, hydrophobic or apolar molecules is suggested to be intercellular diffusion, while the preferred mechanism for small, hydrophilic molecules is suggested to be transcellular diffusion [25].

Dye diffusion into hair fibers is largely influenced not only by fiber architecture [24], but also its condition [2, 26] (i.e., if it is damaged/more porous) as well as the molecular size, shape, and polarity of the dye [4], and solvent employed [3]. Solvents can induce hair fiber swelling and thus enhance free volume within the hair fiber and promote the diffusion of dye within. Hair fiber swelling can also be influenced by pH [27]. Swelling is lowest at the isoionic point of hair (5.5 [27]), or the pH at which there is no net protein charge or charge is equilibrated [3, 4, 6, 20, 28]. Contrarily, excess negative or positive protein charge will cause the chains to repel one another (or swelling) [27]. The isoelectric point, or the pH at which the amino acid molecules in hair do not migrate in an electric field (or bear no net electrical charge) [3, 4, 6, 20], can also affect the diffusion of dye into hair. An isoelectric point of 3.67, as determined by Wilkerson and co-workers [29], has mostly been cited in the literature. When probing the dyeability of the surface of hair, the isoelectric point is of more importance, while the isoionic point is more

important when considering the dyeability of the fiber as a whole [20]. At a pH greater than the isoelectric and isoionic points, hair bears a net negative charge [3, 4, 20, 28] and vice versa at a lower pH. Hence cationic dye species display affinity for hair under alkaline conditions [3, 4, 10], and anionic dye species display affinity for hair under acidic conditions (see Fig. 3). Reductive and oxidative chemical treatments and increased free lipid content can decrease the isoelectric point [20], and chemical treatments can also decrease the isoionic point [6, 20]. The diffusion of anionic dyes into hair is slow at pH levels exceeding the isoelectric/isoionic points of hair but faster for nonionic and cationic dyes [2].

Concentration, temperature, and viscosity are other factors that will affect dye diffusion [2]. A higher concentration of dye increases the likelihood of dye interaction with the hair fiber, and the higher the temperature, the faster the diffusion of dye. Too high of a viscosity in the dye formulation will inhibit dye diffusion into the fiber.

Permanent Hair Dye Chemistry

Permanent hair dyes are the most popular of all synthetic dyes. They constitute about 80% of the global hair dye market [30–32] due to their ease of application, longevity, gray hair coverage efficiency (100%), and versatility in colors that can be achieved [3–5, 11]. Their efficacy stems from the diffusion of low molecular weight precursors into hair that, upon oxidation, couple together and

Coloration, Hair, Fig. 3 Schematic representation demonstrating isoelectric and isoionic effects on hair and the affinity of anionic and cationic dyes toward hair at different pH levels

produce colored oligomeric species known as indo dyes [2]. The oligomeric species that form inside the hair become too large to be desorbed (i.e., are mechanically entrapped) [2, 4, 5, 12], promoting wash resistance. Required for permanent hair dye formation are the precursors (primary intermediates and couplers) in addition to oxidizing and alkalizing agents. Primary intermediates are typically *ortho*- or *para*-substituted aromatic hydroxy and amino compounds [1, 3–5], while couplers are typically aromatic compounds possessing electron-rich substituents in the *meta* positions [1, 3]. Some examples of exceptions for couplers are naphthols and pyridines [1]. Examples of other precursors can be found in the Hair Dye Substance Database recently developed by Williams and co-workers [14], which is available for download at https://figshare.com/articles/Hair_Dye_Substance_Database_HDSD/_5505856. Couplers, which are essentially colorless, are known as color modifiers, because they play a role in determining the final color achieved [1, 3, 5, 30]. Direct (non-oxidative) hair dyes may also be included in the formulation of permanent dyes to function as “color agents” that modify the color directly [10], enhancing vibrancy [1]. Examples of color agents are C.I. Disperse Blue 1, 2-nitro-*p*-phenylenediamine (red), and 4-nitro-*o*-phenylenediamine (yellow-orange) [10].

A general reaction scheme for the formation of permanent hair dye is shown in Fig. 4. In summary, *p*-phenylenediamine/PPD (1) or

p-aminophenol/PAP (4) is oxidized using an oxidant such as hydrogen peroxide leading to the formation of *p*-benzoquinonediimine (2) or *p*-benzoquinonemonoimine (5) [5]. The conjugate acid of *p*-benzoquinonediimine (3) or the neutral form of *p*-benzoquinonemonoimine (5) is considered the reactive species that results at alkaline pH [30]. The pK_a of 3 is 5.75 [33]. Therefore, it is the less dominant species in the pH 8–10 range of dyeing, and it decreases in amount by tenfold for each unit increase in pH [33]. An alkalizing agent such as ammonia will activate the oxidizing agent [10] and promote hair swelling [34] and the diffusion of the precursors into the cortex [35]. A subsequent electrophilic substitution reaction with 3 or 5 and coupler (6) will occur at the *para* position to the electron donating group (amino or hydroxyl), resulting in the formation of a leuco (soluble) form of the dinuclear indo dye (7) [3, 5]. If $R \neq H$ in the *para* position, the group present in this position will act as a “blocking group” and inhibit further oligomerization [4, 5, 35], giving rise to the insoluble dinuclear dye species upon further oxidation (8) [36]. If $R = H$, 3 or 5 can undergo 1,4-addition with 7 to form a trinuclear indo dye (9) upon further oxidation [3]. The former case ($R \neq H$, or the formation of dimer) results in light shades, while the latter case ($R = H$, or the formation of trimer) results in dark shades [35]. For examples, *p*-toluenediamine (PTD) and 4-amino-2-hydroxytoluene are

Coloration, Hair, Fig. 4 Oxidative coupling of PPD or PAP with coupler to form permanent hair dye. (Note: R₁, R₂, and R₃ are O or NH)

expected to form dimers, while PTD and *m*-aminophenol are expected to form trimers [37]. Isolated dyes from hair have also been of larger molecular weight species [10].

As many as 10–12 precursors can exist within permanent hair dye formulations [3]. Generally, dyes affording darker colors contain the highest concentration of precursors, while light colors contain the lowest concentrations [1]. Initial concentration of dye to form the target colors varies from 0.006 to 7%. The final concentration of dye is diluted upon the use of a developer (contains oxidant), for example, by 50% (for 1:1 mixing). Multiple, competitive reactions occur when there are more than one primary intermediate-coupler pair in the formulation. As a result, the final color seen depends a variety of factors such as the reactivity and concentration of the couplers [33], the diffusion rates and redox potential of the precursors [4], the pH at which dyeing occurs [33], and the starting base color of the hair. Consequently, the practice of hair coloration can be an art.

Color formation is more rapid in the hair fiber than in solution, because peroxide in aqueous solution is a weak oxidant (HOO^-) for primary intermediates like PPD and PAP, and species that are more reactive can form outside of solution [30, 33]. Since the reactions are quite fast, the indo dyes form primarily in the cuticle and outer portion of the cortex, because the precursors do not have time to diffuse deep into the core of the fiber before reacting [10]. The dye, though mechanically entrapped within the hair fiber, can bond to hair through secondary and ionic bonds [2]. Covalent bonding of dye is also possible between nucleophilic regions in hair [10].

Permanent Hair Dye Toxicity Concerns

Permanent hair dye precursors have raised potential toxicity concerns for many years. Indeed, their carcinogenic potential has been a matter of debate since the 1975 Ames study that found a large

number of hair dye products to contain substances that were mutagenic [38]. As a result, there was a major reformulation period during the 1970s and 1980s that resulted in the removal of substances from hair dye products demonstrating mutagenicity [36]. In 2010, the International Agency for Research on Cancer (IARC) published a monograph detailing an extensive epidemiological data review of hair dyes and cancer risk in animals and humans [1]. It was concluded that there is limited evidence from studies involving laboratory animals and occupational workers and not enough evidence in consumers to establish the unequivocal carcinogenic risk of hair dyes. Thus, hair dyes have been designated as “probably carcinogenic to humans” (Group 2A) for occupational workers and “not classifiable to its carcinogenicity to humans” (Group 3) for consumers. The Food and Drug Administration (FDA) also agrees that there is not enough evidence to conclude that hair dyes are carcinogenic to consumers [11, 39]. In addition, the Scientific Committee on Consumer Safety (SCCS) acknowledges that there is no clear evidence of an elevated cancer risk for the use of dyes marketed in the European Union [11].

On the other hand, several precursors are strong/extreme skin sensitizers (or allergens) [40]. Indeed, a recent United States consumer exposure study conducted by Hamann and co-workers identified 106 out of 107 (99%) of commercial hair dye products contained at least one allergen, the average product containing six allergens [41]. Allergens found in most of the products included resorcinol (in 89% of the products), *p*-phenylenediamine/PPD (in 78% of the products), *m*-aminophenol/MAP (in 75% of the products), and *p*-aminophenol/PAP (in 60% of the products). PPD and other precursors can cross-react with benzocaine, black rubber, and other frequently encountered chemicals [41, 42], thereby enhancing skin sensitization potential [43]. Bleaching agents, sulfites, fragrances, and preservatives found in the product formulations can also induce consumer sensitivities [42]. Symptoms such as swelling, inflammation, itching, asthma, renal failure, headache, insomnia, and dizziness [34] can occur within 2–48 h or more, depending on the severity of exposure [41,

42]. Common areas affected include the forehead, neck, and ears. Generally, the scalp itself is not affected, although dye is sometimes located here [42]. Some consumers are more prone than others to develop allergies. For example, likelihood increases with age in addition to frequency of use. In regions where the dyeing of beard hair is more common, men are more likely than women to develop allergic responses, but typically women are more prone to developing allergies since they use hair dyes more frequently. Consumers that color their hair using darker shades are also more likely to develop an allergy, because the associated products contain the highest concentrations of allergens [43].

Unfortunately, there is no “cure” to hair dye allergies, although temporary relief of symptoms can be obtained through the use of medications [42]. The consumer is simply advised to avoid dyes that they may have sensitivities toward or to avoid the use of permanent hair dyes altogether [44]. However, there are certain challenges with heeding this advice. For example, the North American baseline patch test series only includes PPD, but other hair dye product components may induce allergenic reactions [41]. Consequently, hair dye allergies may be undiagnosed. Also, the consumer may be confused by terms that may be used to market hair dye products, such as “natural,” “healthy,” and “protect”. Some of these products could still cause skin sensitivity.

The environmental effects of hair dyes cannot be ignored, since their manufacture and consumption generates a large amount of waste [45]. Indeed, PPD, *p*-toluenediamine (PTD), resorcinol, and Bandrowski’s base (see Fig. 5), a known mutagen [38] that arises from the self-coupling of PPD, was found in wastewater collected from a hair dyeing facility [46, 47].

Alternative Permanent Hair Dye Precursors and Coloration Technologies

Alternative permanent hair dye precursors and coloration technologies have been proposed to eliminate permanent hair dye safety concerns, many of which have been extensively reviewed

Coloration, Hair,
Fig. 5 Structure of
 Bandrowski's base

Coloration, Hair,
Fig. 6 Chemical structure
 of 2-methoxymethyl-PPD

by Morel and Christie [3]. Alternative permanent hair dye precursors include substituted derivatives of PPD and PAP, mono-, di-alkyl and 6-substituted resorcinols, heterocyclic-based pyrimidines and pyridines, and pyrazoles. Benzene ring substitution in the *ortho*-position of *p*-phenylenediamines and *p*-aminophenols was one strategy attempted to reduce the toxicity of these compounds while enhancing their color performance on hair. Some new strategies to oxidize precursors without the need for harsh oxidizing agents were also reviewed. Few newly proposed alternative precursors have had commercial success. One example is 2-methoxymethyl-PPD [11], which introduces a methoxymethyl side chain onto PPD [48] (see Fig. 6). This alternative primary intermediate was recently commercialized due to its excellent color performance on hair and moderate sensitization potential compared to PPD and PTD [48], even for some individuals demonstrating PPD and PTD allergies [49].

Li and co-workers synthesized a series of tetrahydroquinoline and dihydroindole couplers (see Fig. 7) reacted with either PPD, PTD, or PAP to afford blue or red shades [35]. The tetrahydroquinoline derivatives, in particular, *N*-methyl-7-amino-1,2,3,4-tetrahydroquinoline, exhibited color vibrancy and superior wash resistance and stability to light compared to the dihydroindole derivatives and commercial hair

dyes studied. The toxicological profile of the new couplers was not reported, though.

Alternative permanent coloration technologies, despite some individual successes, have yet to prevail over the economy and efficacy of conventional permanent hair dye precursors. One interesting proposed alternative permanent hair coloration technology involves the use of infused biocompatible spherical silica nanoparticles (206 nm average diameter) with commercial red acid dye (Telon Red M-BL) [26]. Sampaio and co-workers adopted this technology and found the nanoparticles penetrated only bleached hair fibers. Coloration was performed at pH 4.5, which afforded more potential protein binding sites for the colorant. Significant color loss was seen during the first six washes, due to dye removal from the outermost layers of the hair fiber. Beyond six washes, color loss was minimal up to thirteen washes.

Hair coloration strategies have been developed to take advantage of the polymerization of dopamine on a solid surface with the aid of a metal-complexing agent. This technology mimics the natural hair coloration formation process (see **Melanin** chapter). One advantage of this technology is the low skin sensitization potential of polydopamine (PDA), which has been found to cause no edema or erythema in the rabbit skin protocol [50]. Another benefit is the strong binding interaction potential of complexed PDA with hair keratin, thereby enhancing the wash resistance of the colorant. In a study conducted by Im and co-workers, a PDA metal complex was developed on hair with the aid of FeSO₄ [51]. The resultant complex was black in color, and little color change was observed for colored hair fibers that were soaked in a soap solution up to 30 min. Other colors on hair could be achieved by replacing the

Coloration, Hair, Fig. 7 Alternative permanent hair dye precursors developed by Li and co-workers [35]

Fe^{2+} with an ion such as Cu^{2+} . More recently, Gao and co-workers developed a PDA metal complex on hair with the aid of CuSO_4 and H_2O_2 [50]. The resultant complex was black in color, rapidly formed (ca. 5 min), and was wash resistant up to 30 shampoos.

Another interesting hair dyeing technology was proposed by Ochiai and co-workers, who examined the viability of certain acid dyes as novel permanent hair colorants when applied to hair with metal salts such as AlCl_3 [13]. Acid dyes studied included C.I. Acid Orange 7 and C.I. Acid Red 52, which are traditionally non-oxidative hair dyes. Reportedly, the dyes outperformed conventional semipermanent and permanent dyes in terms of color brightness and longevity. The toxicological profile of the dyes was not reported, though.

Some other interesting potential permanent hair coloration technologies include the use of graphene-based dye [52], the use of catechinone, a water-soluble colorant obtained from tyrosinase reaction with (+)-catechin [45], and the addition of coloring agents to the hair follicle during growth and development [5]. The use of photonics to develop color on hair without the presence of a physical colorant is a research avenue yet to be explored. Although successful research efforts to inhibit or reverse the process of graying may decrease the need for the design of alternative

hair dyes, such endeavors have proven quite challenging to achieve [11]. Despite the above exciting developments, there remains a need for alternative permanent hair coloration strategies that are environmentally friendly. Thus, studies in this important arena continue. This work includes the use of cheminformatics modeling to facilitate the screening of large dye databases for potential hair dye alternatives [53].

Coloration, Ink-Jet Printing

Yi Ding¹ and Lisa Chapman²

¹Donghua University, Shanghai, China

²North Carolina State University, Raleigh, NC, USA

Synonyms

Continuous Ink Jet (CIJ); Cyan, Magenta, Yellow, or Black (CMYK); Direct to garment (DTG); Drop-on-Demand (DOD); Piezoelectric ink-jet (PIJ); Raster image processing (RIP); The international textile machinery exhibition (ITMA); Thermal ink-jet (TIJ)

Definition

Textile ink-jet printing is a noncontact method of jetting colorants directly onto fabric. This technology can be used for roll-to-roll, or direct-to-garment (DTG) printing, and is a rapidly emerging alternative to screen printing, particularly for sampling and smaller runs. By eliminating the screen preparation process, ink-jet printing allows more flexibility in the printing process, provides capability for fine line detail, a near infinite number of colors, freedom from repeats, and the ability to engineer a print design within a garment or furniture marker. The fine line detail and increased number of colors can produce a near photographic

image on the textile substrate, enabling new product categories.

Ink-jet machines are typically classified by printhead and are continuous ink-jet (CIJ) and drop-on-demand ink-jet (DOD). With a CIJ printer, the ink is projected through the nozzles on the printhead at a constant speed, and under a constant pressure. With a DOD printer, the ink drops are ejected only when needed. The two main mechanisms used to generate drops in a DOD system are piezoelectric ink-jet (PIJ) and thermal ink-jet (TIJ).

Technology Development

Ink-jet technology was first described by Lord Rayleigh in 1878 [1], as a “nonimpact dot matrix printing technology in which droplets of ink are jetted from a small aperture directly to a specific position on a medium to create an image” [1, 2]. Commercialization of this technology was first seen in paper printing applications and drove many of the advances in ink-jet printing technologies throughout much of the mid-twentieth century. In the early 1970s, the first printers were developed specifically for the textiles industry; most notably Milliken Company introduced the Millitron printer for carpet printing. The Millitron, had fairly low print resolution, only 20 dots per inch (dpi), however this resolution was suitable for pile fabrics [3]. In the mid/late twentieth century, systems for digital ink-jet printing for textile substrates were developed, with sampling as the main use [4].

As demand for textile ink-jet printing increased, advancements occurred in print resolution and printing speed. The ink-jet printer first

used for roll-to-roll textiles was based on dye jets controlled by solenoid valves. Introduced in 1987, this printer had CIJ heads, and operated on the binary principle with four printheads (cyan, magenta, yellow, and black) that scanned across the fabric attached to a rotating drum. Print production average done hour per square meter. Multilevel charge systems were introduced later on with a multiple array of printheads to increase output [5]. In 1999, a TIJ water-based ink printer was launched with a 300 dpi resolution, and the print speed could reach 12 m²/h. In 2003, the Artistic 2020 printer premiered at the ITMA expo. This printer was suitable for reactive, disperse, acid dyes and pigment inks, with 600 dpi capability, and a print speed of 30 m²/h [6, 7].

Currently, ink-jet printers can be classified into four categories, based on speeds ranging from 4 m²/h to greater than 120 linear m/min (see Table 1). Digital textile printers that employ single-pass printhead systems print on the substrate as the fabric is fed under a fixed print unit. Single-pass printers print at significantly higher speeds (up to 120 linear m/min) than scan-type printer that print by moving the printhead carriage back and forth. In single-pass printing, each printhead station jets one color, cyan, magenta, yellow, or black (CMYK), and up to four additional stations of colors can be added such as blue, green, violet, grey, red, or orange.

The footprint of single-pass printers is considerably larger than scanning mode printers; however, the speed of single-pass printers justifies the large square footage, as these printers are capable of printing up to 70 m²/min. By ITMA 2019, single-pass printers achieved speeds of 120 linear m/min and had resolutions of up to 1200 dpi and

Coloration, Ink-Jet Printing, Table 1 Printer classifications by production speed

Printer	Speed	Colorant capability				
		Acid	Disperse	Pigment	Reactive	Vat
Class 1	4 m ² /h to 12.5 m ² /h	x	x	x	x	x
Class 2	16.5 m ² /h to 33.5 m ² /h	x	x	x	x	x
Class 3	58.5 m ² /h to 334.5 m ² /h	x	x	x	x	*
Class 4	70 m ² /min	x	x	x	x	*

*Under development

Coloration, Ink-Jet Printing, Fig. 1 Double-sided digitally printed silk fabric from Atexco

some even had capability of double-sided printing [8], see Fig. 1.

System Components

There are several components that comprise a textile ink-jet printing system:

1. An assembly of inkjet printheads, which generates streams of microscopic ink droplets and directs them to their target position on the fabric. The ink can be pressurized at 3–5 MPa for the CIJ printhead but is supplied at essentially atmospheric pressure and is most commonly used for DOD printheads [5]. The majority of piezo-electric printheads used in textile ink-jet printers are manufactured by companies such as Seiko Epson, Ricoh, Konica Minolta, Kyocera, and Fuji Dimati [8]. HP manufactures thermal printheads for DOD printers.
2. A mechanism that feeds and presents the fabric to the traversing ink-jet printheads ensures perfect registration and alignment throughout the fabric, even for delicate and unstable substrates such as knits or fine silks. The printing system may also have functions to preheat, dry, and/or heat-set the printed fabric after printing, with

capability of rolling up the output fabric smoothly with even tension.

For roll-to-roll printing, the fabric roll is unwound at the same speed as the printer and wound under tension to another roll after printing. With difficult-to-handle fabrics, for example, lightweight fabrics such as 5–10 mm silks, a stiff paper backing is lightly adhered to the pretreated fabric, to facilitate the fabric feed in the roll-to-roll printing system. More recently, a sticky-belt fabric feeding system was developed, which utilizes a special chemical-coated belt to support fabrics, reducing distortion or shrinkage of the substrate [9].

3. Software, including printer drivers, raster image processing (RIP), and color management systems, is needed to convert computer-based designs into the electronic signals which control the ink-jet printhead and machine. The software also has color management functions to ensure reproducible results with different batches of fabric, and to provide a total interface with the other components of a digital design, sampling, and production environment.
4. Ink-jet colorants, whether pigments or dyes, need to be milled and filtered to much finer tolerances than colorant used for conventional screen or roller printing. The inks for textile ink-jet printing must exhibit key physical and chemical properties to be suitable for jetting, including purity, viscosity, surface tension, conductivity, pH values, foaming properties and particle size, temperature response characteristics, and long shelf life without settling or mold growth [10]. Inks must not corrode surfaces or form deposits within the printhead. Also, the chemical properties of the colorant determine the extent of the interaction with the textile substrate, which is enhanced by pre- and post-treatment steps [11–13], see Fig. 2. Specifically, the ink must be readily and evenly adsorbed onto the individual fibers and yarns of a fabric after printing, providing the required color and intensity characteristics. Properties such as washing, light, and rubbing fastness and wicking resistance are also enhanced.

Coloration, Ink-Jet Printing, Fig. 2 Digitally printed polyester fabric before (top) and after (bottom) pretreatment

Commercially available colorants in textile ink-jet inks include reactive, acid, and disperse dyes, nano-scaled pigments, and vat dyes. A four-color set comprised of cyan, magenta, yellow, and black (CMYK) has become the industry standard for textile ink-jet printing. Additional colors can be added to the standard ink set, to increase the color gamut and reduce total ink consumption [9, 14]. An example of the color gamut derived from a four- and six-color set is shown in Fig. 3.

5. Textile substrates employed for printing normally require a pretreatment step because the fabric construction (weave or knit) can cause wicking problems, leading to a higher ink penetration and reduced color strength on the substrate [5]. Pretreatment and a subsequent post-treatment step improve print quality [9], providing the adhesion and reactivity needed to meet end-use specifications such as target color and fastness properties.

Coloration, Ink-Jet Printing, Fig. 3 Color gamut comparison for representative four- versus six-pigment color sets

Textile ink-jet printing offers opportunities for exciting new products to enter a variety of apparel, garment badges and labels, interior textiles, carpets and floor coverings, technical textiles, flags and banners, and industrial graphics markets [15]. This technology also offers opportunities to capture personalization and quick response to fashion changes, as it provides lower costs for shorter print runs and just-in-time delivery [16].

The development of high-speed digital (ink-jet) printers provides a process that is competitive with rotary screen printing in terms of speed and cost, while offering a competitive advantage when printing shorter runs or multiple color ways [17]. Also, no screens are required, which means all costs to engrave screen, make paste, strike-offs, downtime, and wastage are eliminated. Further, less space is required for industrial printing, with no need for operations associated with film masters, stencils, screens, or plates. The multicolor registration of ink makes possible an unlimited repeat size and number. Inventory and pollution control costs are decreased tremendously. Therefore, ink-jet

printed fabrics would offer a game changing strategy for the international textile printing industry.

Coloration, Mordants

Martin Bide

Department of Textiles, University of Rhode Island, Fashion Merchandising and Design, Kingston, RI, USA

Definition

Probably the one word that those otherwise unfamiliar with dyeing know is “mordant,” and it is derived from the Latin word “mordere” (to bite) with the implication that such a compound forms a link between dye and fiber. However, given the complexities of the dyeing process, it is difficult to write a simple definition for “mordant.” The concept is rooted in history, when only natural fibers and natural dyes were available, and scientific understanding was insufficient to explain fully the functions of the various materials used to provide dyeings that were fast to washing, sunlight, etc. As that understanding has developed, the need for mordants has declined to the point where they are commercial oddities. For the purposes of this chapter, the definition is as follows:

A mordant is a substance applied to a textile substrate in parallel with the dyeing process that modifies the interaction of dye and fiber (and remains present in the subsequent dyed material) to provide better uptake, better fastness, and/or a wider range of colors than would otherwise be achieved.

Nevertheless, there are substances that fall into this definition which are not called mordants and some substances described as mordants that do not fit the definition. O'Neill in the 1860s [1] suggested that a mordant should “exert an affinity for the fibrous material to which it is applied, and,

... an attraction for coloring matters,” and this is largely in agreement with the definition given here but implies that the attractions are simultaneous which is rarely the case. Shore [2] gives a definition based on the twentieth-century commercial practice but recognizes the implicit ambiguities.

From the above definition, it is clear that mordants compensate for some lack of substantivity or fastness of a dye. The watershed between a

dyeing world that relied heavily on mordants and one that was becoming relatively mordant-free coincides with the move from natural to synthetic dyes. Mordants were the means of getting good results from natural dyes that were not “designed” for dyeing textiles. Mordants were used for centuries to achieve remarkable results. That strong historical aspect complicates the definition, as our more recent understanding of the chemistry behind the dyeing process has revealed that substances formerly included in the broad scheme of mordants do not truly behave as such.

For several decades prior to the full development of synthetic dyes, chemical knowledge was increasing, and as new elements were identified and new compounds prepared, a wide range of substances were tested as mordants to expand the coloration technology of natural dyes. Even after the first synthetic dyes were developed, their usefulness was broadened by the use of mordanting materials. A notable development occurred in the 1880s, when a new group of synthetic dyes was named “substantive dyes” (later “direct dyes”), because they were substantive toward and dyed cotton “directly” *without* the use of a mordant. Since then, the skill of the chemist has obviated the need for mordants by creating dyes that not only have color but also have the molecular features required to provide dye-fiber substantivity, ultimate insolubility, or functional groups to react covalently with the fiber. The result is a much-simplified (and more efficient) dyeing process that readily provides fast colors.

The (synthetic) dyes form groups that were codified in the second edition of the Colour Index in 1956 [3]. One such group was “mordant dyes.” These dyes were applied to wool in conjunction with a chromium mordant, but their use has lessened as environmental concerns over the use of heavy metals, such as chromium, increase. Together with the very limited use of natural dyes, it is not surprising that mordants are a rarity in (commercial) dyeing today. Current use of mordants is largely confined to home and craft dyeing.

Synthetic dyes were well established before the development of synthetic fibers, and thus when

such fibers were introduced, dyers had mordant-free processes with which to dye them. With one or two exceptions, mordants have been almost exclusively associated with the dyeing of natural fibers. In some cases when materials have been used to improve the interaction of dyes and synthetic fibers, they have not been referred to as mordants, even though they fulfilled essentially the same function.

Overview

In a dyeing process, dyes are soluble (or sparingly soluble), and a (textile) substrate (fiber, yarn, fabric) absorbs the dye, through forces of attraction, from an external solution [4] (► [Coloration, Textile](#)). The sum of the attracting forces is referred to as substantivity. The concept of “substantivity,” relating to dyes that impart color without the use of a mordant, is attributed to Bancroft [5] and significantly predates the development of synthetic dyes, even though inherent substantivity is rare in natural dyes. Substantivity also contributes to the subsequent resistance of the dye to removal under in-use conditions (► [Coloration, Fastness](#)).

A dyer seeks to achieve a steady and even uptake of dye by the substrate. For a given dye/substrate/machine, this is achieved with control of temperature, agitation, and liquid volume, augmented with dyebath additives. Such adjuncts to the dyeing process provide the correct ionic strength (as electrolyte), pH (acids and bases), and moderation of the dye-fiber-water interactions (often surfactants). While it may not be obvious, similar interactions take place in textile printing with dyes, albeit in the confines of a small volume of print paste, which will also include substances (“thickeners”) to control its rheology and balance the ready transfer of paste onto the fabric with the need to maintain a sharp printed “mark.” These various dyeing and printing adjuncts, however, do not fall under the definition of mordants. They remain within the exhausted dyebath or print paste at the end of the process and are lost from the colored fiber in any subsequent rinsing.

Natural Fibers

As mentioned earlier, the use of mordants was and is largely confined to the use of natural fibers, which fall into two distinct groups: protein (wool and silk) and cellulosic (chiefly cotton and linen). Mordants behave somewhat differently for each of these two groups of fibers. Protein fibers comprise many different amino acids with a range of functional groups that provide binding opportunities for colorants of all kinds [6]. Natural dye users overwhelmingly prefer to dye wool for this reason. Mordants are/were nevertheless widely used to provide better fastness and to broaden the range of colors obtainable from a limited number of natural dyes. Cellulose lacks this inherent affinity for natural colorants, and with the notable exceptions of indigo (which does have substantivity, albeit low), turmeric, archil, saffron, and annatto (which have fastness limitations), natural dyes do not readily dye cellulose. Mordants provide the main means by which cellulose may be satisfactorily dyed with natural dyes.

Natural Dyes

Many natural organic substances are colored, and a few of those colors can be employed as dyes. Chemically, many are flavonoid derivatives (Fig. 1), with anthraquinones (Fig. 2), carotenoids, and indigoids also providing useful dyes [7, 8]. Most provide yellow-orange-brown colors; bright reds are less common, and blues are rare. Fastness varies, especially to light, and is influenced by the choice of mordant and efficiency of fiber-mordant-dye binding.

Over time, expert European dyers learned how to apply these dyes with the appropriate mordants to give bright and fast colors, versus those that were less satisfactory. Thus, Venetian dyers were of either greater or lesser arts. French dyers were “au grand teint” and “au petit teint” [9]. In each case, the former were the more expert. Global exploration would eventually provide better natural dyes. Woad was the original blue in Europe,

Coloration, Mordants, Fig. 1 Luteolin, the main coloring matter of weld (“dyer’s rocket”). Potential binding sites for mordants are arrowed

Coloration, Mordants, Fig. 2 Alizarin, the main coloring matter of madder. Potential binding sites for mordants are arrowed

replaced with indigo (the same essential colorant) when that became available. Reds and purples were from madder and kermes, the latter replaced when cochineal from Central America was discovered. Yellows were from weld or Persian berries, later from quercitron found in North America. Dye woods (sappan, Brazil, cutch, fustic, logwood) were also important. Other than woad or indigo, these colorants were used in conjunction with a mordant. The inventive chemistry that allowed these natural dyes to give good results when they were all that was available, today, allows craft dyers and researchers to reexamine a wide range of plants as sources for natural dyes in the supposition that these dyes are somehow more “sustainable.”

Mordants for Cotton and Cellulosic Fibers

Since few natural dyes display substantivity toward cellulosic fibers, the use of mordants is essential to achieving satisfactory dyeings and prints with those dyes. Two sources [10, 11] give a valuable survey of the use of mordants on cellulosic substrates when such mordants were being widely used. The most effective mordants were metallic salts that could be applied as a soluble salt, rendered less soluble, and subsequently undergo complex formation with the dye. For dyeing a solid color, the fabric would be padded with this metallic salt. For printed designs, the metallic salt would be incorporated into a print paste. Such a metal salt, if it remained soluble, would redissolve in the subsequent dyebath: the dye-mordant complex formed in the bath would tend to deposit on the textile surface and later be prone to rub off. Thus, some means of reducing the solubility of the metal ion and keeping it in place on the substrate as the dye-mordant reaction took place in the dyebath were required, especially in a printed substrate where reserve of the unprinted (white) areas was essential [1].

Insolubilization could be accomplished in a number of ways. Using aluminum as an example:

1. A soluble aluminum salt such as aluminum sulfate or aluminum potassium sulfate (potassium alum) could be neutralized with carbonate or bicarbonate to produce a “basic aluminum sulfate” or “basic alum,” respectively. Padding with this, followed by treatment with ammonia, would precipitate aluminum hydroxide on the fiber. Alternatively, the mordant metal could be precipitated as the corresponding phosphate, arsenate, or silicate [10].
2. Co-application of a complex anionic substance would provide insoluble complex salts. Tannins from a range of sources were ubiquitous in this regard, from galls, myrbolam, cutch, or (later) purified tannic acid, resulting in a deposit of aluminum tannate [10]. The effectiveness of “mordants” based on modified vegetable oils (usually castor or olive oil) was

probably due to a similar mode of action: Turkey red dyeing is discussed below. (Note: cotton will absorb tannic acid from solution, and cotton so treated does dye more readily, so tannic acid does have a moderate effect as a mordant by itself.)

3. Salts such as aluminum acetate could be “aged” in moist conditions under which acetic acid would be lost, generating an insoluble metal hydroxide. A “dunging” (originally with cow dung, later with synthetic alternatives such as sodium phosphate or arsenate) process would both complete the fixation of the mordant and remove unfixed mordant. This process was especially important in printing [11].

Given the above example, it is not surprising that nineteenth-century references to mordants usually include a similar application of a metal salt that would subsequently be reacted with a second metal salt to generate a colored inorganic compound. For example, a “lead mordant” (lead acetate) applied by padding and drying would be passed through a bath of sodium or potassium dichromate to produce insoluble yellow lead chromate [12]. This precipitation reaction is sufficiently rapid that the insolubilization of the original “mordant” was not required. This use of the word mordant is not current.

Excluding, therefore, the use of the word mordant as a component of a precipitated mineral colorant, aluminum and iron were used most extensively as mordants for natural dyes on cotton in both dyeing and printing. Stannic salts were occasionally used. Both iron and aluminum could be produced as the acetate. Iron could be directly dissolved in pyroligneous (acetic) acid, while a reaction between aluminum or ferrous sulfate and lead acetate or calcium acetate would generate a lead or calcium sulfate precipitate and leave aluminum or ferrous acetate in the supernatant liquid. These acetate solutions were referred to as purple liquor (for iron) and red liquor (for aluminum), based on the colors they would produce in a madder containing dyebath [13]. Tin salts were common adjuncts to aluminum salts, where they prevented dulling by the presence of small amounts of iron salts. Chromium salts were

less easy to precipitate in the fiber and were not extensively used, other than to provide a black color with logwood in which processed dye and mordant were often applied together (compare the dyeing of wool by the metachrome method discussed below). Texts available during that time also include a range of other metal salts among the discussions of mordants for cotton but indicate that their function is often that of an oxidizing (Cu, Cr) or reducing (Sn) agent.

The immersion of a mordanted fabric in a dyebath would allow the formation of a dye-metal complex. (This is discussed in greater detail under mordant dyeing of wool, below.) In a fabric print, the unmordanted dye in the dyebath would inevitably stain the unmordanted portions of the fabric, and the fastness of the dye-mordant complex in the colored areas is indicated by its ability to survive the subsequent “clearing” of dye from white parts of the printed fabric by extensive washing processes.

As outlined above, the process is reasonably straightforward, although requiring care and attention to achieve successfully. Some idea of the added complexities and obfuscation generated by ignorance can be gleaned from any reading of the history of Turkey red dyeings. Modern science has identified the final product on the fabric as a 2:1 alizarin/aluminum complex anion with an associated calcium cation [14] (Fig. 3). But for years, the process was shrouded in mystery, and much money was paid for supposed recipes for this color [13]. As originally described, the process involved many steps carried out over a period of weeks or months. The deposit of fatty acids (from olive or castor oil) was a part of the process, leading to references to “oil mordants.” Advances during the nineteenth century such as the introduction of synthetic alizarin, “Turkey red oil,” and chemical bleaching methods allowed for the dyeing to be carried out in days instead of months [15]. The structure of Turkey red oil and its role as part of the mordanting process have recently been (re)examined [24].

Given the difficulty in dyeing cotton and other cellulosic fibers with natural dyes, it is not surprising that as scientific knowledge increased in the early nineteenth century, many attempts were

Coloration, Mordants, Fig. 3 “Turkey red” (alizarin-aluminum complex). Compare Fig. 2, alizarin.

made to modify those fibers to improve their dyeability. Dyers of the nineteenth century attempted such modifications to cotton. The substances have been described as “mordants” [11], but if these modifications are carried out in bulk, separately from the dyeing process, they stretch the definition somewhat. The modifications were presumably prompted by the greater substantivity of dyes for protein fibers and mostly consisted of depositing protein material onto cotton. Albumen from eggs or blood, gelatin, and casein and lactarine from milk were used in these attempts. The efforts were classified as “animalizing” cotton. Such modifications continue to this day: cotton can be pretreated to have cationic groups and readily takes up anionic dyes [16]. Cotton so treated is not referred to as being mordanted, however.

A new category of mordants for cotton was required when the first synthetic dyes were introduced following Perkin’s synthesis of mauveine in 1856. For almost 30 years, many of these new dyes comprised what are now classified as acid and basic dyes, which have no substantivity toward cotton. Dyers were obviously eager to make use of the bright colors they offered, and the precipitation of tannic acid with salts of antimony (in the form of antimony potassium tartrate,

or “tartar emetic”) on the fiber provided an anionic substrate with which cationic basic dyes would interact sufficiently well to provide substantivity and fastness [15].

A subplot in the saga of cotton and mordants occurs in efforts in the twentieth century to improve the fastness of the direct dyes. These efforts comprised aftertreatments to a dyed material. Mordants typically are applied before the application of dye; these aftertreatments are not usually regarded as mordants, but the interactions have factors in common with those that dyes and mordants undergo. For example, anionic direct dyes for cotton could be aftertreated with cationic compounds to form a salt complex with reduced solubility and better fastness to washing. Direct dyes with functional groups capable of chelating metal ions might be aftertreated with copper or chromium salts: a dulling of shade would be compensated by improved fastness to light and (less so) to washing. This technique is technically indistinguishable from the application of mordant dyes to wool by afterchroming but is not regarded as an example of the use of mordants [3].

The same (natural) dye will provide distinctly different colors depending on which metallic salt it interacts with. The functional groups on the polypeptide chains that form the keratin of which wool is composed include groups, notably carboxylic acid, with which metal ions can form bonds, holding them in place during subsequent interaction with the dye. Thus, the insolubilization required for cotton mordants is not needed. For those reasons, the number of metal salts useful as mordants is greater for wool than for cotton and includes tin, copper, and chromium. Wool additionally has sulfur-containing amino acids that will reduce (or maintain in a reduced form) polyvalent metals: thus, chromium is applied as dichromate (Cr^{6+}) and interacts with dye as Cr^{3+} . Tin is applied and interacts as Sn^{2+} . Dye recipes often include mild reducing agents (tartrate, oxalate) to assist this.

Natural dye structures (Figs. 1 and 2) have quinonoid, hydroxyl, and carboxy groups capable of chelating metal ions. Synthetic mordant dyes have the same groups plus nitrogen-containing (amino and azo) groups (Fig. 4). Dyes are usually

Coloration, Mordants, Fig. 4 CI Mordant Black 11 (14645). Sites for coordination with chrome mordant arrowed

bi- or tridentate ligands, and the metals they interact with usually have coordination numbers of four or six.

Mordant Dyeing of Wool

As discussed earlier, the use of a mordant for applying natural dyes to wool has less to do with achieving substantivity than it has to providing better fastness than the unmordanted dye and to extending the range of colors available. Mordants for wool were (and are) overwhelmingly metallic compounds: no parallel with the animalizing reactions on cotton discussed above was developed. The non-mordant cationization of cotton is perhaps echoed in comparatively recent research to render wool dyeable with disperse dyes [17].

The chelation reactions on the fiber between chromium and synthetic mordant dyes have been the most widely studied, but the principles involved are the same as those between other metals and natural dyes. Dye makers simplified the mordant dyeing process by carrying out the dye-metal binding during dye manufacture and selling “premetallized” dyes (also known as metal-complex acid dyes), and the chemistry of this complexation is more easily studied in the absence of the fiber [2, 18, 19]. While these are overwhelming complexes involving chromium and cobalt, iron and aluminum have been examined as less polluting alternatives, and copper-complex direct and reactive dyes are used on cotton. Dye-metal (1:1) complexes were

introduced in the early twentieth century, with 2:1 dye-metal complexes introduced in mid-century. Chromium has a coordination number of six: the dye molecule in 1:1 chromium complexes provides three ligand interactions (binding sites), and the remaining three ligand sites are occupied typically by water. It has been suggested that these sites can interact with groups on the wool fiber, although evidence is lacking. If they do so, however, this would represent one of the few instances where the common metal model of a mordant as a bridge linking dye and fiber is relevant. The metal atom in a 2:1 complex has no such spare binding capacity and achieves fastness via large molecular size and low solubility. In theory, either 1:1 or 2:1 complexes might be formed by a mordant dyeing process, but evidence suggests that the 2:1 complexes predominate. Whether produced on the fiber or as a metal-complex dye, the resulting complex is more stable to light and has limited solubility and thus good fastness to wet treatments. The traditional method of mordant dyeing of (natural) dyes on wool involved pretreating the wool with a solution of the metal salt and subsequently introducing the mordanted wool into a dyebath. This sequence is still used for dyeing natural dyes on wool today. When synthetic (mordant) dyes were developed, their varied chemistry could generate the range of shades required, and the need for multiple metal mordants declined, with chromium (as dichromate) providing the best fastness, and this became the main choice for mordant dyeing using the “chrome mordant method” [20, 21]. Interest in making the processes more efficient took advantage of the independent substantivity of both dye and mordant. They could be applied together (the “metachrome method”) in a manner reminiscent of the chromium-logwood black dyeing of cotton. While this is a one-bath process and seems an obviously more efficient means of application, it is limited to dyes that exhaust well at neutral pH, are not precipitated by dichromate, and do not reduce Cr^{6+} to Cr^{3+} [20]. Eventually, the process in which the dye was applied first and subsequently treated in a bath of dichromate ions became most widely used as the “afterchrome” or “topchrome” method. As discussed above,

this is technically indistinguishable from the after-treatment of a direct dyeing on cotton with a copper (Cu^{2+}) salt.

Synthetic Fibers

Given the similar dyeability of nylon to wool and the search for fastness in nylon dyeings, it is not surprising that chrome mordant dyes have been applied to nylon. The lack of reducing groups in nylon means that a reducing agent is required in the process to convert Cr^{6+} to Cr^{3+} [22]. Chromium-complexed dyes are rarely applied to nylon today. In an interesting twist, the tannic acid/antimony mordant for basic dyes on cotton has been applied as an aftertreatment (“back-tanning”) to improve the fastness of acid dyes on nylon, although no interaction with the dye is suggested.

Acrylic fibers, introduced in the 1950s, were initially difficult to dye in dark shades with acceptable fastness. Before the development of modified basic dyes, an early solution was the so-called cuprous ion method in which the fiber was treated with a solution of Cu^+ ions, and the fibers were then dyeable to dark shades with acid and direct dyes. A number of variations were published, including the application of dye and copper ions simultaneously and the use of reducing agents, but the process was superseded before becoming a standard dyeing method. This is clearly a mordant dyeing technique, although none of the descriptions of the time refer to it as such [23].

Conclusion

Mordants have a long history in enhancing the coloration of textile fibers. They are essential in the dyeing of cellulosic fibers with natural and basic dyes and improve the fastness and color range obtainable on wool with natural dyes. With the advent of synthetic dyes, their use became restricted to the chrome dyeing of wool, but they have found little value in any dyeing of synthetic fibers. They are rarely used in large-

scale commercial dyeing today but are widely used among home and craft dyers for whom the use of natural dyes remains popular.

While the details may sometimes be hard to unravel from historical or unscientific descriptions/interpretations, the majority of mordants are metal ions (most notably of Cr, Al, Fe, Sn, Cu) that react with dyes to form coordination complexes of low solubility and better fastness. Other useful mordants are those that interact ionically with dyes, again forming a lower solubility complex.

Definition

Dyeing can be described as the uniform application of colorant(s) to a coloring medium. The coloring of textiles may involve mass pigmenting (involving compounding), dyeing, and printing processes. The coloring medium in textile dyeing may take different physical forms (such as loose fiber, yarn, tow, top, woven, nonwoven and knitted substrates in open width or rope form), whereas in printing colorants are added to selected regions of the medium which is usually in a fabric form. Dyeing of homogenous fibers should result in a uniform solid color. Multicolored effects may be obtained by dyeing a blend of different fibers, bi- or multicomponent synthetic fibers, or via multiple colorant or illuminated discharge printing. In a technique known as space dyeing, colorant(s) can be applied from nozzles that inject different dyes to yarns and force steam in the vessel, thus generating a multicolored pattern.

There are difficulties encountered in controlling the physicochemical changes that occur during dyeing when attempting to maximize color yield, levelness of dyeing, color fastness, etc. Therefore, a vast sub-technology of specialty chemical auxiliaries is used in preparation for dyeing and in the dyeing process itself, such as levelling agents, dispersing agents, antifoams, etc., as well as auxiliaries specifically designed for aftertreatments. Moreover, from the practical standpoint, methods of applying colorants to the coloring medium can be broadly divided into batch, semicontinuous, and continuous processes. These are discussed in more detail in the following sections.

Dyeing Process

The science of coloration entails several domains including chemistry, physics, physical chemistry, mechanics, fluid mechanics, thermodynamics, and others. Devising the most efficient dyeing process typically involves several concerns including machinery design, preselection of dyes of compatible properties, use of pH versus time profiles, selection of liquor ratio, flow rate and

flow direction reversal times, and design of temperature versus time profiles. It is thus clear that dyeing is a complicated process with many different phenomena occurring simultaneously that require a suitable level of control.

When a textile fiber comes in contact with a medium containing a suitable dye under suitable conditions, the fiber becomes colored, the color of the medium decreases and that of the fiber increases, thus resulting in the dyeing of the substrate. True dyeing occurs when the dye is absorbed with a decrease in the concentration of dye in the dyebath and when the resulting dyed material possesses some resistance to the removal of dye by washing [1], rubbing, light, and other agencies.

Coloration of textiles is not limited to the simple impregnation of the textile fiber with the dye that occurs during the initial phase of the dyeing process. A dye is taken up by a fiber as a result of the chemical or physical interactions between the colorant and the substrate. Many dyes for textiles are water soluble, and their molecules are dissociated into positively and negatively charged ions in aqueous environments. The uptake of the dye by the fiber will depend not only on the nature of the dye and its chemical constitution but also on the structure and morphology of the fiber.

Textile Fibers

A fiber is characterized by its high ratio of length to thickness and by its strength and flexibility. Fibers may be of natural origin or formed from natural or synthetic polymers. They are available in a variety of forms. Staple fibers are short, with length-to-thickness ratios around 10^3 – 10^4 , whereas this ratio for continuous filaments is at least several millions [2]. The form and properties of a natural fiber such as cotton are fixed, but for man-made fibers, a wide choice of properties is available by design. The many variations include staple fibers of any length, single continuous filaments (monofilaments), or yarns comprised of many filaments (multifilaments). The fibers or filaments may be lustrous, dull or semi-dull, coarse, fine or ultra-fine, circular or of any other

cross section, straight or crimped, regular or chemically modified, or solid or hollow.

From a processing standpoint, natural fibers have a number of inherent disadvantages. They exhibit large variations in staple length, fineness, shape, crimp, and other physical properties, depending upon the location and conditions of growth. Animal and vegetable fibers also contain considerable and variable amounts of impurities which must be removed prior to commencing dyeing. Man-made fibers are much more uniform in their physical characteristics. Their only contaminants are small amounts of slightly soluble low M_w polymer and some surface lubricants and other chemicals added to facilitate processing. These are relatively easy to remove compared to the difficulty of purifying natural fibers.

Water absorption is one of the key properties of a textile fiber that influences their coloration. Protein or cellulosic fibers are hydrophilic and absorb large amounts of water, which causes radial swelling. Hydrophobic synthetic fibers, such as polyester, however, absorb almost no water and do not swell. The hydrophilic or hydrophobic character of a fiber influences the types of dyes that it will absorb. The ability to be dyed to a wide range of hues and depths is a key requirement for almost all textile materials.

Another important property of a textile fiber is its moisture regain, which is the mass of water absorbed per unit mass of completely dry fiber, when it is in equilibrium with the surrounding air, at a given temperature and relative humidity. The regain increases with increase in the relative humidity but diminishes with increase in the air temperature. Water absorption by a fiber liberates heat (exothermic) and will therefore be less favorable at higher temperatures. The heat released is often a consequence of the formation of hydrogen bonds between water molecules and appropriate groups in the fiber. When the final regain is approached by drying wet swollen fibers, rather than by water absorption by dry fibers, the regain is higher. For hydrophilic fibers such as wool, cotton, and viscose, the relatively high regain values significantly influence the gross mass of a given amount of fiber. This is significant in dyeing. Amounts of dyes used are usually expressed as a

percentage of the mass of material to be colored. Thus, a 1.0% dyeing corresponds to 1.0 g of dye for every 100 g of fiber, usually weighed under ambient conditions. For hydrophilic fibers, the variation of fiber mass with varying atmospheric conditions is therefore an important factor influencing color reproducibility in repeat dyeings.

Stages of Coloration Process

Most textile dyeing processes initially involve transfer of the colored compound, or its precursor, from the aqueous solution onto the fiber surface, a process called *adsorption*. From there, the dye may slowly *diffuse* into the fiber. This occurs through pores or between fiber's polymeric chains, depending on the internal structure of the fiber. The overall process of adsorption and penetration of the dye into the fiber is called *absorption*. Absorption is a reversible process. The dye can therefore return to the aqueous medium from the dyed material during washing, a process called *desorption*. Besides direct absorption, coloration of a fiber may also involve precipitation of a dye inside the fiber, or its chemical reaction with the fiber. These two types of processes result in better fastness to washing, because they are essentially irreversible.

Dye Transport from the Bulk Solution to the Fiber Surface

Dyeing is a process which takes time. The transfer of a dye molecule from the dye solution into a fiber is usually considered to involve the initial mass transfer from the bulk dye solution to the fiber surface, adsorption of the dye on the fiber surface, followed by diffusion of the dye into the fiber as depicted in Fig. 1.

When a fibrous assembly is immersed in a dye solution, the rate at which the dye is taken up is generally dependent upon the extent to which the liquor is agitated and tends to approach a maximum value when the stirring is vigorous.

The transfer of dye from the bulk solution to fiber surface is fast, and the rate generally increases

Coloration, Textile, Fig. 1 Dye transfer from bulk solution into a fiber [3]

with increasing the flow rate. The adsorption equilibrium is also rapid, so it is usually assumed that the overall rate of dyeing depends on the rate of diffusion of the dye into the fiber. Inadequate control of the rate of dye adsorption will result in unlevel dyeings unless the dye can subsequently migrate from deeply dyed to lightly dyed regions of the substrate [1]. Therefore, the control of the first two stages of the process, namely, the initial mass transfer from the bulk solution to the fiber surface and adsorption of the dye on the surface, is important for a level dye distribution throughout the substrate to be achieved.

A fundamental issue in dyeing is to ensure that the dye liquor penetrates all parts of every fiber and is distributed within the substrate as evenly as possible. In practice, however, there may be differences in fibers, to a greater or lesser extent, because of natural or process-related parameters. These variations are of major importance, since, in wet processes, changes in regional density of the substrate result in variations in the degree of dye penetration and differences in flow rate which can lead to shade differences in dyeing.

The influence of agitation in increasing the rate of dye uptake is dependent in large measure on the hydrodynamic complexity of the system. Unfortunately, flow through the substrate cannot be described in any simple fashion with fibrous assemblies, due to the extreme complexity of defining the flow of liquor through a mat of fibers or through yarns or cloth.

In spite of the complications of real systems, some of the principles governing the process may be elucidated by consideration of simple ones, e.g., a plane sheet or film of material immersed in dye liquor whose direction of flow is parallel to the sheet. On making contact with the dye liquor, dye is adsorbed by the film so that the neighboring liquor becomes deficient in dye; dye is transported to the surface by dispersion from the bulk, but the quantity transferred is modified by the speed at which the liquor passes through the film.

Calculations of the rate at which the fibers can take up dye require knowledge of the flow pattern of the liquor before analysis of diffusion may be attempted. Experimental investigations of flow of dye liquor through masses of fiber lead to the conclusion that, at the common rates used in dyeing, the flow is streamline rather than turbulent, so attention may be confined to streamline conditions.

Intermolecular Forces Operating Between Colorants and Textile Material

The strongest dye-fiber attachment is that of a covalent bond. Another important interaction between dyes and fibers includes electrostatic attraction, which occurs when the dye ion and the fiber have opposite charges. Hydrogen bonds may also be formed between a specific range of colorants and textile fibers. In addition, in nearly all dyeing processes, van der Waals forces and hydrophobic interactions are involved. The combined strength of the molecular interactions is referred to as the *affinity* of the dye for the substrate. The substantivity of the dye is a less specific term and is often used to indicate the level of exhaustion (which is described in the following sections) [4]. Thus, substantivity is the attraction between the substrate and a dye under precise conditions where the dye is selectively extracted from the medium by the substrate. Different types of textile fibers require different kinds of dyes, and in general, dyes which are suitable for one type of fiber may not dye other types effectively.

Levelness

Levelness is the uniformity of dye distribution (and hence color) on textiles. Two fundamental mechanisms contribute to a level dyeing. One is the initial sorption of dye during the dyeing; the other is the migration of dye after initial sorption on the fiber. An initial level sorption will lead to a level dyeing. An unlevel sorption may be corrected if sufficient migration takes place. These mechanisms are affected by dyes and chemicals, by textile substrate, and by controlling the parameters of the dyeing process such as dyebath pH, liquor ratio, flow rate, and temperature. Some dyes are more likely to level out, especially if they are small and do not have a high degree of affinity towards the substrate; other dyes on the other hand tend to be much less likely to migrate. These are often dyes of large size or with strong affinity towards the substrate.

Dyeing of Various Textile Materials

Textile fibers can be dyed at various stages of production such as loose fiber, top, tow, yarn, fabric, or garment. The levelness requirements for dyeing loose fibers are less strict than for dyeing at the yarn stage or at later stages, since further processing of the loose fiber results in some mixing of the dyed fibers, e.g., during carding or gilling, which improves the levelness of the resultant color. For yarn dyeing levelness is more critical because while the yarn will be made into fabric, either by knitting or weaving, or used in the construction of carpets, any unevenness in the dyeing of the yarn will show in the finished goods. In the case of fabric and especially garment dyeing, the process will be less forgiving and variations will have to be remedied in different ways, either by over dyeing the substrate to a darker shade or by stripping the color and reapplying the colorant. Dyeing textiles at earlier stages of production such as loose fiber also reduces the degree of flexibility in response to market needs. Garment-dyed material can reach the market quickly and meet the rapidly changing

demands of the market, whereas in the case of fibers or yarns, typically several additional processes have to be completed before the dyed material reaches the consumer. In the case of substrates with striped patterns yarn dyeing is quite common. When blending dyed yarn with undyed yarn to produce a woven pattern, it must be considered that subsequent bleaching and scouring may be needed. Thus, dyes of suitable fastness properties, to bleach and various agencies, have to be employed to ensure no staining of adjacent white regions occurs. Dyeing of fabrics and garments with variations in fabric density or stress can also result in systematic unlevelness. A common type of unlevelness in dyeing of nylon fabrics is known as Barré which appears as stripes across the substrate. A specific visual appearance test method to rate the degree of Barriness of dyed substrate has been introduced over the years.

Batch, Semicontinuous, and Continuous Coloring Processes

There are three main types of processes for the dyeing of textile materials: batch, continuous, and semicontinuous. Batch processes are the most common method used to dye textile materials and often depend on the type of equipment available and the weights or lengths of the material to be dyed. Batch dyeing is often called exhaust dyeing because the dye is gradually transferred from a relatively large volume dyebath to the material being dyed over a long period of time. Batch dyeing, therefore, involves applying a dye from a solution or a suspension at a specific ratio of liquor to textile substrates where the depth of the color obtained is mainly determined by the amount of colorant present in relation to the quantity of fiber (known as L:R or liquor to goods ratio), although other factors can also influence the overall dye uptake. Batch processes are thus designed for specific quantities of substrate from few grams to several hundred kilograms. Batch dyeing of most natural fibers is carried out under atmospheric pressure conditions. Operations may also be carried out under elevated pressures. For

instance, in the batch dyeing of polyester substrates, high temperatures (HT), around 125–130 °C, and correspondingly elevated pressures are required if the use of carriers is to be avoided. High-pressure beams, jets, and jigs can be used. Although such equipments tend to be more expensive than conventional atmospheric pressure equipments, their cost is more than offset by the omission of carriers. At high temperatures the diffusion rate of the dyes is high enough to produce satisfactory shades in a dyeing time of about one hour. Batch dyeing of polyester, however, can give rise to some bruises and pillings due to hydraulic and mechanical impacts during high temperature dyeing process. Generally, flexibility in color selection in batch dyeing is high, but the cost of dyeing is lower the closer the dye application is to the end of the manufacturing process for a textile product. Two examples of a common type of batch dyeing machine known as beck or winch (shallow-draft and deep-draft winches) are given in Fig. 2.

Semicontinuous dyeing is carried out in a continuous range where the substrate is fed into the dyeing range from one end and collected at the other. In semicontinuous processes typically fixation and washing steps are carried out

discontinuously. Pad rolls transfer the colorant that is picked up from a trough into the substrate, and the process is based on impregnation of the substrate followed by fixation of the colorant. The pressure applied by rolls to impregnate the substrate can be adjusted to squeeze the excess liquor out of the substrate and obtain the required wet pickup percentage. Since the initial uniformity of dye deposition on the substrate is critical for a level dyeing, padding rolls responsible for the transfer of the colorant onto the substrate must have a uniform surface with no indentations. The pressure across the rolls should also be adjusted and controlled regularly to ensure the uniformity of color transfer onto the substrate. The dyeing range may include cans or alternative forms of dryers to prevent migration of dye across the substrate prior to fixation. At the end of the range, the substrate may be rolled onto a beam, covered with plastic sheets, and kept overnight, to enable fixation of the dye, or transported to other sections for subsequent fixation, washing, and aftertreatment operations. Pad-batch dyeing is a specific type of semicontinuous coloration process which is common in the application of reactive dyes to cellulosic substrates. In this process the batch is left overnight to enable the colorant to

Coloration, Textile, Fig. 2 (a) Shallow-draft winch dyeing machine. (b) Deep-draft winch dyeing machine

react with the substrate. Other forms of pad-fix processes may include pad-bake and pad-steam.

Continuous dyeing refers to operations at constant composition involving several application and wash boxes (troughs), where a long length of textile fabric is pulled through each stage of the dyeing process including fixation and aftertreatment. Continuous dyeing operations are common when dyeing large quantities of substrate. This is often carried out on cotton and its blends with synthetic fibers such as polyester. In continuous dyeing processes, fixation and subsequent wash and rinse operations are combined with the coloration process to enable rapid throughputs. Thermofixation (commercially known as Thermosol) which is commonly carried out on polyester and polyester blends is particularly suited to continuous dyeing processes, since it involves padding the dyestuff from dispersion onto the fabric, drying, and then heating the padded substrate to a temperature of 180–220 °C. A specific category of disperse dyes capable of sublimation is employed for this purpose. At such temperatures, diffusion rates of sublimated dyes are so high that a few seconds suffice for adequate penetration of dye molecules into the substrate. Several variables, however, affect the final shade of the dyed fabric during the thermofixation process. Some of these variables are Thermosol period, temperature, type of disperse dyestuff, and pad bath auxiliaries.

In continuous printing processes, colorants are applied to specific sections of the cloth using a number of techniques that may include roller, flatbed, and rotary screen printing systems to obtain a preset design. Dye fixation is carried out by steaming or baking the printed material followed by washing to remove surplus dye, thickeners and any other auxiliaries.

The details of the dyeing process can vary considerably between different types of textile materials employing different types of dyeing equipment. For example, the maximum permissible rate at which the temperature of the bath can be raised may be determined by the relationship between the rate of circulation of the dye liquor and the rate of transfer of the dye from bath to fiber such as in the dyeing of yarn in hank dyeing machines.

The criteria for choosing a dyeing process vary and may include the following:

- Shade range
- Fastness requirements
- Quality requirements and control
- Cost
- Equipment availability
- Dye selection

The aim of a successful dyeing process is to achieve the desired shade, at the right price, with sufficient levelness, whether dyeing loose fiber, yarn, or piece goods, with sufficient color fastness to withstand both processing and consumer demands, but without adversely affecting the fiber quality. Of these, an acceptable level of uniform dye uptake at all parts of the substrate may be the most important criterion.

A typical dyeing process may be divided into several steps as follows:

- Establishment of equilibrium between associated molecular dye and single molecules of dye in solution
- Diffusion of monomolecular dye to the diffusional boundary layer at the fiber surface
- Diffusion of dye through the boundary layer at the fiber surface
- Adsorption of dye at the fiber surface
- Diffusion of the dye into the fiber interior
- Desorption and readsorption of dyes (migration)

These steps form a reversible equilibrium system. Each of the six steps can influence the levelness of dyeings. A complete quantitative analysis of the effects of many factors which influence the levelness of dyeing would require the development of a mathematical model involving a significant number of parameters. This is, however, a very difficult task. For practical applications, one may initially try and identify a few variables, which are thought to have a larger impact on levelness and restrict the development of the model to the effects of these few most important variables.

The Donnan equation involves nine factors: the concentration of dye in fiber, the concentration

of dye applied, the liquor ratio, the distribution of ions between solution and fiber, the ionic charge on the dyestuff molecule, the internal volume of the fiber, the affinity of the dye, the gas constant, and the dyeing temperature. All together, these terms describe the dyebath conditions.

To obtain reproducible dyeings, whether this is on a laboratory, pilot plant, or bulk scale, the following factors in the dyeing process must be controlled or measured:

- Quality of water supply
- Preparation of substrate
- Dyeability of substrate
- Weight of substrate
- Moisture content of substrate at weighing
- Selection of dyes
- Standardization of dyes
- Weighing of dyes and chemicals
- Dispensing method for dyes and chemicals
- Moisture content of dyes
- Liquor to goods ratio
- Dyebath additives
- pH of dyebath
- Machine flow and reversal sequence
- Time/temperature profile

Various workers have placed different degrees of emphasis on each of the above factors and also on the factors which are not listed above. There may also be disagreement on the mechanism by which any one of these factors operates. Furthermore, it should be noted that the parameters in this list are not quite independent, and in some cases the effect of two of these factors may be considered as one effect.

Exhaustion

Dyeing is carried out either as a batch exhaustion process or as a continuous impregnation and fixation process. In exhaust dyeing, all the material is in contact with all the dye liquor from where the fibers absorb the dyes. The dye concentration in the bath therefore gradually decreases. The degree of dyebath exhaustion as a function of time describes the rate and extent of the dyeing process. For a single dye, the exhaustion is defined as

the mass of dye taken up by the material, divided by the total initial mass of dye in the bath. For a bath of constant volume, this can be expressed by Eq. 1:

$$\% \text{Exhaustion} = (C_0 - C_t)/C_0 \quad (1)$$

where C_0 and C_t denote the concentrations of dye in the dyebath initially and at some time, t , during the process, respectively.

Exhaustion curves, such as that shown in Fig. 3, may be determined at a constant dyeing temperature, or under conditions where the temperature and other dyeing variables are changing. For many dyeings, a gradual increase of the dyeing temperature controls the rate of exhaustion, aided possibly by the addition of chemicals such as acids or salts. In cases where the dyes in the deeply dyed fibers are not able to desorb into the bath and then be redistributed onto paler fibers, such control is essential to ensure that the final color is as uniform as possible. Such redistribution of dyes is called migration.

The slope of a dyeing exhaustion curve (Fig. 3) defines the rate of dyeing at any instant during the process. The rate of dyeing gradually decreases until, if dyeing is continued long enough, an equilibrium is reached where no more dye is taken up by the fibers. There is now a balance between the rates of absorption and desorption of the dye. The equilibrium exhaustion is the maximum possible exhaustion under the given conditions. The lack of any further increase in exhaustion does not necessarily mean that a true equilibrium exists. It is possible for the dye in solution to be in equilibrium with the dye located on the outer surfaces of the fibers. True equilibrium only exists when the dye in solution is in equilibrium with the dye that has fully penetrated into the center of the fibers. Dyeings rarely continue to this point since it may take a relatively long time to attain. In fact, many commercial dyeings barely reach the point of constant exhaustion.

There are two basic methods of achieving a level exhaustion dyeing in any dye/fiber system; the first is by dye migration, and the second is by controlled dye exhaustion. The first method involves exhausting all of the dye onto the fiber and then allowing it to migrate between the fibers

Coloration, Textile,**Fig. 3** Dyebath exhaustion as a function of time [5]

in order to “level out” the dyeing. These are dyes which are able to migrate from the fiber back into the liquor and then transfer back to the fiber. This redistribution of dye improves the levelness of the dyeing and normally takes place when the dye liquor is at the boil. In this method the dye is not completely exhausted onto the substrate, and this can lead to poor reproducibility of color, and hence, additions of dye to correct the final shade are often necessary.

The second method is to ensure that the dye is exhausted in a level manner from the start of the dyeing. In this method, the dyeing rate is controlled by changing the parameters of the dye bath at a controlled rate so that the dye is deposited on the yarn in a uniform manner throughout the substrate. Careful control of these parameters, such as dyeing temperature, pH, or amount of electrolyte and flow rate, is often necessary to obtain level, well-penetrated dyeings. This is essential if the dye initially absorbed is unable to migrate from heavily dyed to poorly dyed areas during the process.

Exhaustion Profiles

Variation of the concentration of dye in the dyebath during the dyeing is referred to as the

exhaustion profile, and the shape of this profile has been believed by many researchers to be the most determining factor in levelness of dyeing.

Exhaustion control has been developed theoretically and in the laboratory by several workers. These workers used knowledge of the dyeing kinetics to devise a time/temperature profile to give a particular exhaustion profile; others have attempted a direct control of the exhaustion rate.

Studies of the theoretical basis of the relationship between levelness of dyeing and the rate of dye uptake by textile substrates were initiated in the 1950s and the 1960s. Since then there have been many investigations into the methods of controlling the exhaustion of dye bath in order to improve levelness. This has been an area of much disagreement among researchers.

Linear Exhaustion Profiles

Carbonell et al. [6] developed a mathematical representation of various exhaustion profiles and went on to calculate practical time/temperature profiles that would result in linear exhaustion profiles. Later work aimed at establishing detailed kinetic relationships in order to carry out

“isoreactive” dyeings, in which the dyeings have a linear exhaustion profile.

Cegarra et al. [7] later modified this approach to apply it to dyeings that used continuous addition (or integration) of dye into the dyebath. These dyeings were carried out at constant temperature, using a predetermined dye addition profile to achieve linear exhaustion. This method was defined as Integration Dyeing, which can be used to control the dye absorption during the integration, so as to avoid the possibility of initially fast and anomalous absorption, which may cause unlevel dyeings. In practice, this method is often used to improve the levelness, when all the dyes are added at the beginning of the process.

Several authors have stated that linear exhaustion is most likely to give a level result and developed a control strategy for automation of a dyeing machine such that the percentage exhaustion per circulation never rises above the critical value for levelness.

Other Exhaustion Profiles

The use of linear exhaustion profiles for the control of dyeing process is by no means generally accepted. A number of researchers have stated that a rapid uptake at the start of the process, with a gradual slowing of the exhaustion thereafter, should give a better result than a linear profile. The argument has been that the critical part of the exhaustion phase is the final phase, where the amount removed from the bath is large compared to that remaining, leading to a greater risk of unlevelness. Two profiles of this type, i.e., exponential and one with the exhaustion proportional to square root time, have been suggested.

Experimental work suggests that both exponential and square root profiles give a clear improvement over both a linear profile and a standard constant temperature ramp dyeing. It has been recommended to devise a reliable concentration monitoring system to control the exhaustion process. Despite the suggested strategies this is still an area requiring further research and development.

Practical Difficulties Involved in the Dyeing Process

There are some practical difficulties in achieving a quality dyeing when considering dyeing process control. These are briefly described in the following sections.

Dyeing Rate

Dyeing rates are of greater practical significance than the exhaustion at equilibrium because continuation of dyeing to equilibrium is not economical. Long dyeing times increase the risk of fiber damage and dye decomposition, particularly at higher dyeing temperatures. On the other hand, very rapid dyeings will usually result in the color being unlevel. This implies that dyeing processes should be neither too slow nor too fast. In order that dyes are used economically and as little as possible is wasted in the dyehouse effluent, the dyer prefers a high degree of exhaustion in a relatively short dyeing time. However, dyeing must be controlled so it is not so rapid that it is difficult to produce a level dyeing. If there is a strong affinity between dyes and fibers and the conditions are not controlled, a rapid strike of dyestuff will occur which will often result in unlevel dyeings. To control the rate of dye uptake, a number of dyeing parameters, including temperature, pH, electrolyte concentration, and agitation among other parameters may have to be controlled.
